LECTURES ON SURGERY,

Delivered at St. Bartholomew's Hospital,

By WILLIAM LAWRENCE, F.R.S.

LECTURE XXIX.

Malignant diseases—Schirrus—Cancer—Carcinoma.

THE affections, gentlemen, of which I have hitherto spoken, are all of them of a curable nature; and in many instances, though attended with great temporary disturbance of the part, and with a serious influence on the system at large, yet the derangement is of a temporary kind; and after going through a certain process the part recovers its functions, or at all events, even if it have become seriously injured in that respect, it may recover so far that the life of the individual is preserved. I now proceed to mention some affections that seem to be essentially of a destructive character—in which there is not the same salutary tendency as in those that we have hitherto considered; not the same natural disposition to recovery after going through the diseased process, but where the nature of the action tends to the destruction of the textures of the organ in which it is seated, and which even proceeds to the destruction of life. Such seems to be the essential character of the affections that I am now going to describe to you; and hence they have been called *malignant diseases*, in opposition to the former.

The diseases which we call *cancer*, *fungus hæmatodes*, and *melanosis*, all of them agree in the two points that I have now mentioned; that is, they completely destroy the natural texture of the part in which they take place, and they also proceed to affect other parts besides those in which they primarily originate, by which extension they destroy the life of the individual. In these leading

features, cancer, fungus hæmatodes, and melanosis, severally agree; and hence they are very commonly described together, and have been regarded by some as one affection. There is, however, an essential difference between them: although they have the same destructive tendency in relation to the parts and the life of the individual, yet they differ in the nature of the changes which they produce in the affected part, and they differ in the age of the individuals whom they attack, as well as in respect to certain other points in their course and termination.

It is only of late years comparatively that these different affections have been distinguished from each other, and indeed even now they are very often described together under the term cancer. I find this is the case in some of the most modern French works: for example, in the French dictionary of medicine, in twenty-one volumes (which, by the way, is a very excellent work), in the article Cancer, I observe the several affections now alluded to are all grouped together, being considered as coming under that denomination. There is a work, entitled "*Recherches sur le Traitement du Cancer par la Compression*," &c. by M. Recamier, of the Hotel Dieu, in two volumes, published this year, in which he has described as cases of cancer not merely those that we should assign to cancer, according to our acceptation of the term, but also cases of fungus hæmatodes and melanosis. I certainly think the arrangement I have now mentioned is defective. There are such obvious distinctions between melanosis and fungus hæmatodes on the one side, and cancer on the other, that it is highly inconvenient to mix them together in one description.

Cancer consists in a peculiar change of structure of the organ in which it is seated, and the principal character of which is an unnatural hardness or induration. It may, or may not, be accompanied with swelling of the part. The change of structure then proceeds into a state of ulceration; it does

not remain limited to the organ in which it has first arisen, but extends to the neighbouring parts. It shews itself in other forms in the internal organs of the body; it produces pain, emaciation, and serious constitutional affections; and by the progress of the local symptoms in the part first affected, and by the increase of those constitutional symptoms, it destroys the patient. The swelling and induration of the part which constitute the first stage of the disease, are denominated *schirrus* or *occult cancer*. The disease is called *schirrus* in that early state of its development. The word *cancer* or *carcinoma* is more properly applied to the ulcerated stage, *carcinoma* being equivalent to what, in common language, is called open cancer. The essential nature of the disease, then, seems to consist in the succession of these two stages—that of induration and that of ulceration. Now the word *schirrus* is applied frequently by modern writers to any hard enlargement of an organ, without considering whether this is of a nature likely to proceed to the subsequent change of *carcinoma* or ulceration. In this sense the word is applied by Boyer, in his treatise on surgical diseases. In his article on the subject of *schirrus*, he merely defines it as enlargement and induration of a part; and says that *schirrus* sometimes proceeds to cancerous ulceration, and in other instances does not.

Now the mere character of hardness is not in itself a proper basis for distinction in pathology. Various affections, different in their essential nature, agree in possessing that single character. The mere circumstance, therefore, of consistence, is not of itself a sufficient ground of distinction on which to establish a particular class of diseases. I think, therefore, it is best to keep to what writers in this country now do, namely, to restrict the term *schirrus* to those changes in the structure of a part which will subsequently ulcerate and become carcinomatous.

Intractable ulcerations affecting the skin, although they may not have been preceded by obvious tumour, or a state of *schirrus* induration, generally pass, particularly in common language, under the name of cancer; in fact, that seems to be the form which cancer generally assumes when it affects the cutaneous texture; so that, perhaps, if we were to employ the term very strictly we should find that we could hardly lay down, as a general rule, the necessity of any previous existence of *schirrus* enlargement.

Now we generally see cancer occurring as a change in some particular organ: however, cancerous structure, that is, *schirrus* enlargement which proceeds subsequently to ulceration, may occur as a newly-formed tumour in any part of the cellular texture of the body, like other tumors; this, however, is not common.

The parts of the body which are most sub-

ject to cancer are, in the first place, the female breast, the stomach, or at least certain parts of it, (the cardiac and pyloric extremities), the rectum, the uterus, the lip, the tongue, the penis, the testicle, and the ovary. These are parts in which *schirrus* occurs primarily; but in the advanced stage of cancer, secondary depositions of a cancerous nature, may take place in a great variety of parts of the body. The absorbent glands commonly become affected; the lungs, the liver, the bones, and various internal parts, may be the seats, in a secondary way, of cancerous affection. It is often stated in the accounts of those parts which are most frequently the seat of cancer that the testis of the male, and the ovary of the female, are among these; indeed, you will find that the testes and the ovaria are often enumerated as parts particularly subject to cancer. This I consider to be by no means a correct representation, if we confine the term cancer to the change I have mentioned; for in that case we should say that *schirrus*, and the subsequent transition into cancerous ulceration, are extremely rare, both in the testes and ovaria.

Now in order to give you a general notion of the nature of cancer, I believe it will be the best plan to describe the course which the disease takes in the female breast; for the observations that I shall have to make to you respecting the nature of the diseased change, its course, and ultimate effects, as well as respecting the ages of those that are subject to it, and the kind of treatment that is appropriate, will be applicable to the disease generally; but we shall understand the matter better by this kind of individual example than if we were to make a series of general remarks.

The disease, at the commencement of its attack on the female breast, by no means presents that formidable character which it shews in its progress and termination; indeed, for a certain period, it exists merely as an indolent swelling in the breast, which is hardly noticed by the individual in whom it takes place. It very commonly happens that the female discovers by accident the existence of a *schirrus* lump in the breast; and that when she first perceives it, it has already attained a considerable size. She finds, perhaps, a lump, the size of a walnut, without being previously aware that any disease existed in the part. In this indolent state the *schirrus* lump will often remain for many months, or even some years—for two or three years, not enlarging nor producing any pain. There is a hard tumor, which is loose and moveable; no discoloration of the skin, and no uneasiness perceived in it. After a time, however, the disease loses this indolent character, and assumes a much more active progress, with symptoms that obtrude themselves on the notice of the patient. The

tumor becomes painful; it increases in size; some degree of heat, and sometimes a degree of redness and swelling of the breast generally, are perceived. When we come to examine the swelling at this time—and this is the period when it is usually submitted to our examination—we find it characterized by a peculiar incompressible hardness, possessing nothing like elasticity to the feel. You cannot compress it; it has almost the hardness of a stone or solid substance. The surface of the tumor is generally uneven, more or less knotted or tuberculated. It is loose and moveable, not adherent to the pectoral muscle or integuments; so that you can move it about easily, and it feels circumscribed. On examining the breast carefully, you usually observe, particularly if the tumor is increasing, that the superficial veins of that side are much larger and more conspicuous than they are on the other side of the chest. Sometimes they almost assume a degree of varicose enlargement, but usually in the active period of the disease there is a marked difference between the superficial veins of the two sides of the breast. The pain at the commencement of the tumor is not in general constant; it generally comes on at particular periods, and then ceases for a time; it is of a darting or shooting character, and such as has been called lancinating. Then the patient is sometimes quite easy; but all of a sudden a sharp darting pain is experienced in the part, and frequently at this period the pain is very severe. About the same time we usually find that the lymphatic glands of the axilla become affected. You find, perhaps, one or more of them enlarged; and some pain is experienced in the gland, of a kind similar to that which is felt in the tumor.

In the progress of the affection we soon find that the disease begins to extend from the circumscribed tumor, of which it at first consists, to the surrounding parts. In the first place the skin becomes adherent to the swelling upon the most prominent point; it is fixed to it; and frequently, in consequence of this, the skin appears to be drawn or tucked in opposite to the swelling, so that you see the situation of the swelling by this retraction of the skin. Sometimes a deep fold is produced by this adherence of the skin to the tumor: at the same time it is not uncommon to observe a retraction of the nipple, so that you find the nipple of the affected breast considerably less elevated than that of the opposite side; sometimes it is, in fact, completely drawn in; and occasionally you find, instead of forming a prominence, that the nipple is situated at the bottom of a depression—the retraction is so considerable. The tumor, after it becomes adherent to the skin, sometimes is also fixed to the pectoral muscle. The cellular texture which intervenes between them becomes consolidat-

ed, and the tumor can no longer be moved laterally on the surface of the muscle. After some time the mammary gland, together with the skin which covers it, and the pectoral muscle, form one hard mass, very firmly connected to the surface of the chest, and not admitting of being moved on the parts beneath it. The swelling in the axilla increases; the disease occupies the whole mass of the absorbent glands there, and constitutes a firm solid tumor, which becomes fixed in the axilla in the same way as the schirrous breast itself is fixed on the chest. At the same period you very probably find that the lymphatic glands that are situated above the clavicle about the root of the neck, become enlarged; and the progress of the affection that I have now described is attended with considerable increase in the sufferings of the patient. The pain that only took place occasionally becomes more constant and more severe, and the health of the patient begins to be affected. As soon as the glands enlarge above the clavicle, you will find that œdematous tumefaction takes place in the upper extremity; in fact, the whole mass of the lymphatic glands connected with the arm, those in the axilla, and those above the clavicle, become the seat of disease. Hence the interstitial absorption of the limb is put a stop to, and œdematous tumefaction is the result. It sometimes increases to a great extent; the limb augments in size; and being accompanied with inflammatory action in the part, it occasions great suffering to the individual.

During the time that this change is going on, the health of the patient becomes considerably impaired. Sometimes, however, before the disease has gone to the state that I have mentioned, ulceration commences in the original tumor, and we find this take place in two ways. Sometimes the ulceration is superficial, and produces but little discharge, which however encrusts, so that there is a kind of scale formed on the surface of the part: this is more particularly the case where the integument is drawn in, in the form of the deep folds that I have mentioned, over the tumor. The ulceration comes on in the form of a crack at the bottom of one of these folds; the discharge that takes place from it encrusts over the surface, so that the patient is hardly aware that ulceration has commenced; but more commonly a nipple-like prominence (one or more) takes place on the surface of the tumor, and becomes of a red colour; the tumor, which before was incompressibly hard, now begins to get soft in the situation of these prominences; the skin becomes thinner and thinner, assuming a livid colour, and finally gives way; and you generally find that a discharge, of an ichorous fetid nature, takes place from the surface. This is the most common form of carcinomatous ulceration. When the skin has given way, you find an

extensive ulceration taking place in the surface of the tumor, and a deep irregular excavation is speedily formed in it. The parts are removed by ulcerative absorption, and frequently there is the appearance of something similar to sloughing, by which the ulcerated cavity is increased—that is, a part of the surface of the sore assumes a kind of ash-coloured appearance, seems to lose its vitality, and separates like a slough. The discharge that takes place, whether the process is of one kind or the other, is never at all like pus—it is always thin ichor, and in general very fetid. When the ulcer has become of considerable size, we usually find that the edge is elevated, and probably everted; there is a large rising margin, and considerable excavation in the centre; the bottom and sides are very irregular, sometimes presenting a bright red appearance, like granulations, sometimes presenting the ash-coloured sloughs that I have mentioned, and in the separation of these it not uncommonly happens that considerable bleeding occurs. This process of ulceration is attended with excessive, constant, burning pain. If the pain has been at all of a variable character before—that is, if the patient has occasionally been free from it—when this kind of ulceration takes place, the pain will be found to be constant and very severe.

When the complaint has arrived at this stage, the most unequivocal marks of serious constitutional affection are perceived. This has been called by some writers the state of cancerous *cachexia*;—the French particularly describe it. We find that the patient is pale, sallow, and has a kind of leaden appearance of the countenance—that there is considerable emaciation—that the pulse is accelerated, and the functions of the stomach and digestive organs disturbed; but the constant and severe pain renders the patient almost incapable of getting rest, and, in fact, a state more or less like that of hectic is produced. In this state it commonly happens that the breathing becomes affected—a difficulty of respiration comes on, cough occurs, and the patient sinks under the effect of the local disorder, and the consequent constitutional disturbance that it produces.

When we examine the part, we find that the natural structure of the mammary gland is no longer recognizable—it seems as if it had been removed, and in the place of it that peculiar texture that characterizes *schirrus*, had been deposited. This texture consists of a very hard dense substance, which approaches in consistence almost to that of cartilage; when you cut through it with a knife, you experience the same sort of resistance that you do in cutting through cartilage—it has a kind of semi-transparency, a slightly yellow colour, and it is so

hard that we can make no impression at all upon it with the handle of the knife; it is quite homogeneous, very dense indeed, and if you cut thin portions of it, you see that it is semi-transparent. In this structure you will generally observe, however, on close inspection, that there is an intermixture of white points and streaks disseminated pretty generally through it.

[Mr. Lawrence here presented a preparation, and remarked that it was a specimen of a tumor which exhibited the character and appearance he had just mentioned; in which, if it were closely examined, notwithstanding the density of the texture, those white opaque streaks that he alluded to were distinctly recognizable.]

Sometimes the cancerous structure appears to us as a distinct and circumscribed tumor, the limits of which are well defined; but in other instances portions of this cancerous structure extend from the original seat of disease into the neighbouring parts, forming a striking contrast in appearance with the adipose substance which separates it from the other textures. The absorbent glands of the axilla assume a similar appearance—they seem to be converted into a texture very much like that of the original tumor.

In the early stage of the affection of the absorbents, it is not unlikely that the glands may be enlarged simply by irritation, just as the absorbents are by the irritation of ordinary disease in a part; but very soon we find that the glands have the same firm, incompressible hardness which belongs to the original tumor, and we find when we come to examine them after death, that they exhibit the same kind of dense or cartilaginous change of structure. However, the changes of structure that take place in cancer, are not confined, in cases that proceed to a fatal termination, to the parts that are the original seat of disease: when we come to examine the body, we find that the absorbent glands that are seated on the interior surface of the sternum, and anterior part of the mediastinum, are enlarged, and that they have undergone a *schirrous* change. The absorbents from the breast partly take their course between the cartilages of the ribs to the inside of the chest, and thus it is that the glands become affected. On dissection we generally find that the cancerous tubercles, if we may so call them, are deposited in the lungs, and not uncommonly in the liver also. These are white and tolerably firm depositions, which are usually found in the greatest abundance immediately under the serous membrane of the lungs; but they are also disseminated throughout the substance of these organs, and not uncommonly similar depositions exist in considerable abundance through the whole texture of the liver. Other internal organs are likewise found occasionally to be the seat of the

disease, such as the uterus. Tubercular depositions of a schirrous kind have been seen connected with the mucous membrane of the stomach, and of the alimentary canal. In proof of the extensive mode in which the system is generally affected in the termination of these cases, I may observe that sometimes bones themselves are changed in their structure—that there is a partial removal of the earthy matter belonging to them, and a deposition in its stead of a kind of cancerous texture. This is found chiefly in cases where cancer has existed for a great length of time, and hence the long bones of the body have sometimes been broken by slight causes, such as turning in bed. The humerus and the thigh bone have in some instances been broken in cancerous patients under such circumstances. I remember seeing an old woman lying in bed, who had been affected with cancer for many years, and in whom the thigh was broken merely from turning in bed. This fracture occurred two or three months before I saw her, at which time she was still in bed with her broken thigh, and apparently no attempt on the part of nature at repairing the injury.—Not long ago there was a case in this hospital, not of a very old person—in fact, of a female under 50 years of age;—she was here some time, and when she first came, appeared stout, and robust in health. Nearly the whole of the sternum, in her case, was affected by cancerous disease. We had an opportunity of examining the parts after death, when it was found that the osseous substance of the sternum had in a great measure been removed, and a dense schirrous texture deposited in its place.—Cancerous tubercles have been known to form even in the brain. Such is the nature of the changes which take place in various internal parts of the body in the advanced stage of cancerous disease.

Now the progress of cancerous disease is not always the same—there are considerable varieties. I have mentioned the progress of it where it appears as a tumor affecting a small part of the mammary gland; but occasionally the same change appears in the entire gland at one and the same time—the whole gland becomes the seat of cancerous disease, instead of the affection being confined to a single small tumor. When the whole gland is thus the seat of the disease, it generally happens that it increases in size, or is swollen, but not considerably so. When, therefore, you see any large swelling of the breast, you may know perfectly well that this is not schirrus. Frequently, indeed, the gland, instead of being increased in size, is diminished—it undergoes a kind of shrinking from absorption. To use the expression employed by the French, sometimes it is affected with *hypertrophie*—that is, enlargement;—sometimes with *atrophie*—

that is, shrinking or diminution. It is in the latter case more particularly, where the shrinking and diminution occur, that the most extensive retraction of the nipple takes place.

Frequently in the progress of the affection, after the mammary gland itself has become the seat of disease generally, or when it has proceeded to ulceration, you have cancerous tubercles developed in the skin in the circumference of the gland—small lumps about the size of peas or beans—little hard knots in the skin. These frequently assume a red or livid colour, become extremely sensitive, very painful, and occasionally go into a state of ulceration. There are considerable varieties observed in the progress of the affection, as to the length of time that it occupies. Generally speaking, we find that it proceeds more rapidly in proportion as the subject is young: its progress is more slow in persons advanced in years. But there are also differences in its progress that we cannot ascribe to the age of the patient, but which seem to arise from some difference in the nature of the affection itself.

I have mentioned that the tumor commonly remains in an indolent state perhaps for several months—or it may even remain in that state for two or three years, or more. When the more active state has begun, we then find that it generally terminates fatally, at all events within two or three years; frequently it ends in a year, or little more, from the time that the more active growth has commenced. I had occasion to remove the mamma of a lady, who first perceived the existence of a tumor in her breast about Christmas 1828; and at the time that she discovered the lump there was also a swelling in the axilla—so that at one and the same time she found out the existence of the schirrus in her breast, and change in the state of the axillary glands, consequent thereon. I removed the part for her. When I came to perform the operation, however, I found a much more extensive disease in the axilla than I had expected when I commenced it; and I mention the circumstance to you as a caution. In these cases you find the whole chain of the axillary glands diseased, when perhaps you only expected to find a single gland enlarged. It is proper, as far as possible, to ascertain this point before you operate. I removed the breast and diseased axillary glands of this lady, but the disease returned in the part, and she died, as nearly as possible, in a year from the time when she had first discovered the tumor in her breast.

There are other instances in which the disease lasts a much longer time. I was consulted by a lady, about 60 years of age, a thin spare woman, who had got a cancerous affection of one breast; and the breast

so affected was smaller than the other, being shrunk in size. The tumor consisted of a small induration, and was completely fixed to the side of the chest. There was a deep fold of the skin crossing along the centre. This fold was about four inches in length, and at the deepest part about an inch and a half in depth, giving a most singular appearance to the part. There was a single gland diseased between the breast and the axilla. Now in this lady the disease had existed, apparently in that state, between six and eight years, and never gave her any pain all that time; and when I saw her it gave her no uneasiness.

A patient died in this hospital during the last summer, in whom disease of a decidedly cancerous nature had existed for about twenty years. In this patient, the whole of one breast, with the nipple, had been destroyed. The parts had been removed partly by absorption and by the cancerous ulceration which had attended it. The same affection had taken place and had nearly destroyed the mamma of the other side also. All the anterior part of the chest, from the clavicle down to the upper part of the abdomen, presented a sort of mass, rather of a carcinomatous substance than of muscle or mammary gland; but, in fact, there was nothing left but an irregular indurated mass, as hard as cartilage, and adhering to the integuments of the chest. When she first came to the hospital there was a large ulceration occupying the interval between the two breasts; there was much pain and inflammation about the parts, and the ulcer was in a foul state; but in other respects she was in good health, and you could not have said that there was any thing the matter with her. She looked well in the face—eating, drinking, and sleeping tolerably well. The application of leeches gave her very great relief; in fact so great, that during two or three months she staid in the hospital the sore almost completely cicatrized. She lost the pain in the chest, and regained her health; so that she went out of the hospital with the sore nearly healed, and she looked so well that a person seeing her dressed, and not knowing the state of her chest, would not have suspected that she had any disease whatever. I mention this to shew that although cancer is to be regarded in general as an incurable affection, yet, under certain circumstances, it does admit of being healed. This patient was out of the hospital some months, and returned again labouring under symptoms of acute inflammation of the chest. She was admitted for this complaint, and died in consequence of it: we had an opportunity of examining her after death. The disease had existed in this individual nearly twenty years. She was about fifty when she died, so that it had begun when she was about the age of

thirty. There was very considerable thickening of the pleura and of the upper part of the peritoneum. It would seem as if this long continued disease in the neighbourhood of these serous membranes had gradually extended to them by continuity, and produced considerable alteration of their structure—a sort of cancerous change of structure, with a granular and indurated surface. There was also in her case a cartilaginous thickening of the pericranium, covering a part of the skull, and a corresponding change of texture of the dura-mater.

In a healthy person the progress of the cancerous disease is often so slow that it does not materially shorten life. You may see a lump in the breast that is decidedly scirrhus—the integuments may become adherent to it, and both become adherent to the chest; a kind of superficial ulceration will take place, attended with slight encrustation; and this state of things will last for a number of years, and perhaps does not apparently accelerate the descent of the individual to the grave. I am acquainted with a lady whom I have seen various times for six or seven years, and who has got an affection of the breast most decidedly schirrous; the glands of the axilla are enlarged, and there are a few slightly so on the side of the neck. She is now about eighty-four years of age, and I do not imagine that when she dies it will be of cancer. There are a number of instances where cancers last a great length of time, where they have begun at a late period of life.

Cancerous affection sometimes arises from external or accidental causes—such as a blow, or some other injury inflicted on the part; but more commonly they appear to arise spontaneously—that is, from internal causes, the nature and origin of which we cannot exactly trace. Last winter I had occasion to remove the breast of a female, in whom the disease had arisen from a blow; and it was an obvious and unequivocal example of the kind. This patient was the wife of a publican, who resided some miles from London. Her husband had been to town, and he brought back a cocoa-nut as a present for his wife; he tossed it to her to catch, but she did not succeed in her attempt to do this, and it struck her a severe blow on the breast. She was previously in good health, and a tolerably robust woman. The breast swelled in consequence of the blow, and became very painful; in fact she suffered so much locally and generally, that her medical attendant found it necessary to bleed her, and adopt other antiphlogistic treatment, under which the general swelling subsided, but the lump enlarged; and in consequence she came to town to consult me. I found a swelling of a hard nature, and an enlargement of the glands of the axilla. I prescribed means for her, on

the supposition of its being merely an induration or enlargement consequent on the injury, and supposed that it would go off. It did not do so, but assumed so decidedly a schirrous character that I recommended an operation. She consented to this, and I performed it; when, to my surprise, I found the whole chain of glands diseased, from the breast to the axilla, and up the side of the neck. The affection was schirrus, with all its characters strongly marked. I removed the breast last December (1828), and she continues well to the present time; so that the operation seems to have been successful.

It has been made a question, whether cancer was a local or constitutional disease? The meaning of the latter phrase is not very clear, or obvious. I rather think, however, we might say that cancer is at one period a local disease and at another a constitutional one. When we see a tumor forming in a small part of the mammary gland, in an individual otherwise perfectly healthy—when we see it not disturbing any function, producing no pain, causing no inconvenience of any kind—I think we must conceive there that the disease is simply confined to the part; and in that condition it is clearly a local disease. When we come to a more advanced period, in which we find the disease shewing itself more or less generally on various other parts of the body—when organs distant from that primarily affected become the seat of disease, we recognize the action of some more general influence upon the frame; and I think we may then fairly admit that cancer is a constitutional disease.

It is an important matter to distinguish cancer from other diseases, and more particularly to establish the diagnosis at an early period of the affection. It is at an early period that we have an opportunity of taking effectual means for the removal of cancer, if, in fact, such means can be taken at any period—a point of which some doubt may be entertained. The sooner, therefore, we can recognize the exact nature of the affection, the better chance we have of applying the means at a time when they may be expected to have the effect of removing the complaint.

It has been observed frequently, that several individuals of the same family have suffered from cancer. In this respect, cancer is like any other affection. Those natural peculiarities of the organs which are transmitted by generation, and which distinguish members of one family, may lead, under certain circumstances, to the occurrence of cancer in them, as they do to phthisis pulmonalis, to affections of the head, or any other forms of disease.

Now the female breast is subject to other enlargements, attended with more or less in-

duration, which, in a very early period, can hardly be distinguished from the enlargement of schirrus. At a very early period, the schirrous tumor perhaps is not immediately under the surface of the skin; it is covered by some part of the mammary gland, and by the integuments covering the breast; so that the sensation of incompressible hardness is not communicated to the hand, or it is not clearly recognizable at the very commencement. Then, as far as I know, the characters we must trust to are the unevenness of the surface—that is, the knotty kind of feel it presents—the sharp shooting or lancinating pains; and when these have taken place, the enlargement and the partially varicose state of the external vessels of the part. The age of the patient in some measure assists us too in the diagnosis; at all events it lends us a negative aid. Cancer does not occur in young subjects; it is very uncommon to see it in patients under thirty. You may very safely conclude, if there is swelling in the breast of an individual under thirty, that it is not schirrus. Sir Astley Cooper states, that, in his extensive practice, he has only seen two instances of true schirrus affecting the breasts of individuals under thirty. I have myself certainly seen the disease in an individual under thirty; for I remember removing the breast of a patient in this hospital under that age. She afterwards had the disease in the other breast, and she died of it pretty quickly. Usually it takes place between the ages of forty and fifty; very often about the period of the cessation of menstruation.

I come next to consider the *treatment* of cancer; and before entering upon this, it appears almost necessary to ask whether cancer—that is, whether schirrus in the first instance, and the ulcerative affection to which it leads subsequently, do admit of being cured at all? A general opinion prevails, that true carcinoma, the disease that has now been particularly described, does not, under any circumstances, admit of being cured. I believe, if the opinion of the most experienced persons were asked on this point, they would have no hesitation in saying that this affection cannot be cured; yet I do not know that we should be altogether justified in laying that position down quite broadly and positively. Such a position might lead us to rest contented, without using any means, in certain cases that perhaps might admit of benefit; it is a discouraging opinion to state in that broad way. In the work that I have mentioned to you, of Baron Boyer on Cancer, I find three rather singular facts, which, as far as they go, rather tend to throw some doubt upon the idea of cancer being incurable. He mentions two instances of tumors, considered to be schirrous, occurring in the breasts of females; in one of which the opinion of Pro-

fessor Dubois and that of M. Dupuytren was taken, as to the propriety of extirpating the tumors. Both of these gentlemen gave a decidedly unfavourable opinion of the operation, grounded on a belief that the disease was decidedly of a schirrous nature, and so far advanced that they thought relapse would be certain if the operation were performed,—and, in fact, they would not operate for that reason. Yet both these patients got perfectly well. I do not know that we can ascribe their cure to the means employed; however a remedy was employed, which has sometimes been considered a very powerful one. This was *cicuta*—*conium*—internally, and applied to the parts on poultices, sprinkled over with the powder of the same herb. This, I may observe, is a remedy which was proposed with great confidence for the cure of cancer, and has been spoken of as possessing great power. However I only state these facts to shew that tumors possessing, in the opinion of persons so eminent and so judicious as MM. Dubois and Dupuytren, all the characters of a schirrous affection, may get well. The third case that he mentions is also very interesting—it is that of a lady aged 48, whose mother died of cancer. She discovered a hard lump in her breast at the age of 48; the skin became adherent to it; it was a hard incompressible tumor, with darting pains. There arose from the surface of the tumor two nipple-like prominences, which assumed a red colour, and seemed as if they were on the point of ulceration, and going into a state of carcinoma. She was in a very bad state of health, and had great dread even of the application of leeches, much more of any thing like an operation, so that she avoided consulting any surgeon; at last, however, she took the opinion of M. Dupuytren. There were then present such symptoms as led him to say most decidedly that it was a schirrous affection, and that an operation was out of the question, for the disease would certainly return if it were performed; he also objected to the application of leeches in the neighbourhood of the tumor, fearing these might lead to cancerous ulceration, in consequence of their bites. Means of no particular consequence were employed to it locally. The tumor in this case did not increase, but kept for some time stationary, and then it seemed rather to diminish. The lady became subject to pains in the head, which at first were somewhat periodical; then they began to be continued, and were only relieved by the application of leeches to the temples. After this had continued for some time (the tumor during that period diminishing), she had an attack of apoplexy, with hemiplegia; she recovered from this, but had three or four other attacks subsequently, and in the fourth of these she died. The tumor by this time had become

reduced to the size of an apricot stone, whereas when M. Dupuytren saw her, it was the size of a hen's egg. The case was examined after death, and the cause of the apoplectic attack was found to be the formation of a cancerous tumor in one of the hemispheres of the brain, about the size of a walnut, of a hard, firm, schirrous texture, but loosely connected to the texture of the brain; indeed it seemed as if it had been floating in the brain, which was softened around it. On examining the part in the breast, there was merely a small shrunk tumor, about the size of an ordinary nut, remaining. In this case I think there can be no doubt but it was a genuine schirrous tumor, which had been diminished by absorption.

The consideration of the treatment we will postpone till the next lecture.

to 33.

MODERN MEDICINE INFLUENCED BY MORBID ANATOMY:

AN ORATION

Delivered on the 57th Anniversary of the Medical
Society of London,

BY LEONARD STEWART, M.D. &c.

Vice-President of the Society.

ALL rational medicine is founded upon the observation of a certain constancy and identity in diseased conditions—on the frequent recurrence of a series of morbid phenomena which have been before noticed: for, if there were no such repetition—no such analogy to be traced—our acquaintance with disease would be continually beginning and ending with each individual case; there could be no general or systematic rules by which to guide our opinion or our conduct—no permanent circumstance to connect the present with the past and the future; all pathology would be consequently purely conjectural—all practice, of necessity also, blind and empirical. And yet it is true, at the same time, that no two cases, on simple comparison, are precisely alike. Even where diseases are clearly made out and appreciated, there is some new proportion in their elements, or some difference, in kind or degree, in their circumstances, which prevents our regarding any one of these complex states as the exact duplicate of another. Nay, the very existence of malady, considered as a matter of separate study and investigation, depends upon a departure from the indefinite and fluctuating bounds of a healthy standard; between which, however, and

the many preternatural modes into which the living system may pass, there exists no accurate line of demarcation. When, then, we are told, in the same breath, of the infinite variation and complication in the particulars of disease, and the absolute necessity for method and arrangement, it becomes an important question to determine, what contrivance can ever reconcile propositions so discordant—what are the characteristic and permanent features of analogous diseases—and which of the associated medical sciences is to furnish us with the true test by which we may know them upon their occasional reappearance? Between these wide and contradictory extremes have been placed the many systems of pathological writers. Finding the impossibility of retaining in the memory an innumerable variety of confused and undigested facts, and convinced that the consideration of isolated cases, whether falling under personal inspection, or recorded in books, would lead to no practical result, they have proceeded to *generalize*—that is, to distinguish among a number of diseases that common and pervading ingredient which renders certain portions of them proper to be grouped into families or classes; and to invent, on this supposed resemblance, rules for judging of similar cases, and treating them in future. This task of forming a coherent abstract from an infinity of loose and fleeting materials, has been the favourite task of the medical world in all ages. Its full attainment has been, however, beyond the grasp of the most powerful minds. But so great is its importance, that many, who have laboured at its accomplishment, have, by the mere attempt, perpetuated their names, and have been directly or indirectly serviceable; for in medicine the conflict of opinions has always tended to elicit truth, and here, as in other pursuits, there is a necessary and constant supremacy of principles over details.

At different periods of the growth of medical science, there has been invariably some one branch of this comprehensive study, or some favourite system, in the ascendant; and the revolutions in professional history have been so frequent and so complete, that each name has ruled in its turn, and every possible scheme has “tasted of empire.”

The school of Hippocrates, with which our era generally begins, taught chiefly the importance of observation and comparison. And even to this day there is considerable deference paid to its immortal founder, as well as to Sydenham, Heberden, and others of its disciples, when their discernment, and good sense, and experience, are considered apart from their deficiency of information upon questions of anatomy and physiology, and other scientific points, which have been more amply illustrated by modern teachers. The dogmatism of the Galenists and alche-

mists—the ill-advised attempts of many other speculators of the mathematical, mechanical, and chemical schools, to demonstrate the application of their own principles to physiological and pathological phenomena, are, on the other hand, remembered only as so many illustrations of this approved maxim, that “the most ingenious way of becoming foolish is by a system; and the surest method to prevent good sense, is to set up something in the room of it.”

The cultivation of anatomy in its various branches—descriptive, general, comparative, pathological—forms the most characteristic feature of modern medicine. The information obtained by studying the physical signs of malady during life, and by collating these with the alterations of structure which are discovered upon dissection, is of a nature more fixed and tangible than any which can be gained from a general observation of symptoms and constitutional influences. With a just prepossession, then, in favour of this, the best foundation of pathological opinion, we may naturally ask, repeating the question which some time back arrested us, will morbid anatomy give us the only basis on which to re-erect our schemes of pathology and practice?

Let it be understood: my inquiry does not relate to the importance and scientific character of researches into the anatomical mechanism of disease. That man must be strangely blind to the value of truth who should call this in question. Neither will this opportunity be taken to string together a number of common-place observations in praise of what, all the world knows, does not, from its indispensable utility, stand in need of such eulogy. But my object is to offer some speculations as to the extent to which opinion has been modified by the cultivation of pathological anatomy;—to inquire whether an entirely new face be given to medicine by this mode of investigating disease? whether, as has been asserted, morbid anatomy bears the same relation to pathology that chemistry does to mineralogy, bringing to light new elements, and establishing new connexions, and throwing into the shade all notions not verified by this more accurate test?

To a certain extent this is doubtless the case. Many lesions of structure are concealed, and even unsuspected, till they are revealed by anatomical research. What are called accidental membranes and adventitious substances, many new and preternatural formations, various interstitial depositions of fluid, certain tubercular maladies, as *melanosis*, and the whole tribe of hydatids, are so many additions to regular organization, completely *parasitic*; and they interfere so little with ordinary function, and are endowed with so little sensibility, that their existence is not known, in many instances,

till upon dissection. Besides, in other cases, where disease is ascertained during life, we are not made acquainted with its full extent, and various complications, till we call in the aid of morbid anatomy. In this way a world of pathological intelligence is opened to modern investigation. To suppose that all the evidence afforded by anatomical researches is merely posthumous—to fancy that pathological anatomy does not tend to discover the disease in any instance, but merely the “blight and blackening which it leaves behind,” would be, however, in glaring opposition to daily experience. On the contrary, there are many occasions where the information obtained by examining disorganized structure, and brought to bear upon new cases, is of such paramount importance during life that a colour is given to the expectations of those partial disciples of this school who have thought that morbid anatomy offered the only clue to the proper knowledge of disease, and that its assiduous study would speedily regenerate the whole system of medicine. For instance, in mechanical injuries—as fracture, or in obstructions—as hernia, the mischief is appreciated by the precise situation and form of disruption or displacement. Here the cause of suffering is clear and definite, the field of investigation and experiment comparatively limited and fixed. With due allowance, then, for differences of constitutional disturbance, the removal of disease, and the disappearance of anatomical lesion, proceed *pari passu*. While on the other hand, in incurable cases, the condition of the part after death bears the most satisfactory testimony to its impaired function and preternatural position. In some of the structural maladies of the eye, and in many of the accidental difficulties attendant upon gestation and delivery, the phenomena of disease are of the nature of demonstrable facts; and until attention be turned to the physical and mechanical character of these matters, all general considerations are of no avail. Again, in topical inflammations—in the maladies of definite regions and organs, as of the pelvic viscera, the circulating and respiratory apparatus, the cultivation of morbid anatomy, together with a careful linking together of physical signs and symptoms, has led to all our scientific knowledge; and we appeal to dissection for a sure corroboration of our clinical predictions. The investigation of the diseases of blood-vessels, which has formed a distinguished part of this study, has been found to explain many obscure points of medical and surgical pathology. It has not escaped the notice of some critics, however, that those who have devoted their attention to the functions and disorders of these organs, have shewn a disposition to isolate them from the surrounding mass of disease in which they may be implicated,

and to ascribe to them an independent agency in the generation of malady not warranted by our ordinary doctrines of the consentaneous action of vital tissues. The physiology and pathology of the brain and nerves have attracted the attention of the most gifted men of the day. While, however, their investigations have yielded an abundant harvest of intelligence of the most interesting and useful kind, it must be allowed that very opposite results have been obtained by their experiments and researches, and that much yet remains to be developed and ascertained.

But, without bounding our notions by these more simple and intelligible positions of disease, we may at once broadly and frankly allow, that in every case of malady, however fleeting and ephemeral, there is of necessity some preternatural state of organs or tissues; that even what are called functional and symptomatic disorders, argue some modification of physical condition. When, however, we would endeavour to determine what this preternatural condition really is, and what are its causes, it must be obvious to any person of reflection that many circumstances must be considered which cannot be made clear by anatomical inspection. Some of the more palpable organic lesions may be detected by the knife; but dissection must not be expected to discover the foundation of maladies characterized by totally different phenomena. How can anatomical researches acquaint us with the alterations in the fluids, the chemical reactions, the various electrical and galvanic operations, the relations, both physical and moral, with external agents, and the many familiar but evanescent changes which are called vital, and of which no physical test can take cognizance? These operations are continually going on, and they conspire to defeat any attempt to measure all diseases by the application of one universal rule. Indeed, in those cases which are acknowledged to be the most favourable to an exact and accurate plan of analysis, there are frequently so many complications, and so many sources of fallacy, that we should be extremely cautious in placing faith in any sweeping scheme which pretends to simplify all possible occurrences.

I am inclined, indeed, to go further, and to question whether this analytical method of investigation be in reality the true road to the due appreciation of many diseases. Analysis may be carried too far, at least for pathological uses. In systems of general anatomy, we see it trace all the tissues to one or two primary elements; so simple, that they cease to represent the modified structure of the organs which are variously constructed from these fundamental materials. Again, these same tissues, when examined chemically, yield merely gases in varying proportions; and pass from our

view as the agents of vital functions. Their proper organic character is destroyed, and in their new shape we cannot recognize them. So also there are results obtained by analysing very closely the anatomical mechanism of some diseases, which may be called scientific, but which have no similitude with the tumult and activity of living pathological phenomena.

On the contrary, many morbid conditions can be made intelligible only by viewing them as a *whole*—by enumerating all their elements—by associating their early history and progress—and by considering their many relations with extraneous and moral agents. In the large family of spasmodic, intermittent, and periodical complaints, there is frequently either no trace of organic mischief, or this is so much the same in all cases, however opposite, so subordinate to other considerations, and so unsatisfactory as an explanation of the peculiar and mutable character of the maladies during life, that we are naturally disposed to attend to more liberal and extended views of disease. In hypochondriasis, hysteria, and epilepsy, the true condition cannot always be appreciated by a direct inspection of physical signs, without calling upon the testimony of the past, and accumulating every concurrent circumstance. This is notoriously the case, too, with insanity, which, in many instances, cannot be seen, and measured, and defined, but yet can be practically judged of and appreciated. We can give no exact detail of its mechanism, but are not on that account less able to feel and describe its nature and character.

Again, how important to the true discernment of delirium tremens and of puerperal mania is an acquaintance with predisposing and physiological causes! How essential to diagnosis in gastrodynia, gout, neuralgia, is a departure from routine notions, and in distinguishing common from rheumatic and specific inflammations and malignant taints!

In many diseases of the skin, too, where so much is displayed to the view, it is impossible to decide what to think, or what to do, without careful research into their occult causes; and yet the local obstruction of this important and constantly active apparatus is as much an *organic lesion* as the affections of a mucous, or serous, or any other tissue.

There is another difficulty: a disease may be latent, or imperfectly developed—and we must view it through the medium of its connexion with contemporaneous events. We occasionally find, too, that out of a succession of cases even (say of small-pox, or scarlatina), no one instance shall fairly combine all the characteristic ingredients which class under any established nosological definition. In every individual case some one element will be wanting, some anomaly in the accus-

tomed manifestation of the disease will occur, or some complication with which we are not familiar. So that, in default of a due assemblage of symptoms, or when there are more present than we consider proper to the intrinsic disease, we have to recur to what we recollect of other better examples—to rectify perception by conception—to bear in mind an ideal model, which is not fully represented by any one actual case, but requires selection and combination from others, before the proper association of signs and tokens be presented to the judgment.

I am at the same time aware that, in our art at least, this disposition to create a perfect whole out of a number of disjointed parts, and to give unity and coherence in theory to what is scattered and irregular in reality, has often led to the most arbitrary, artificial, and unsubstantial hypotheses—that is to say, where it has been in excess, and indulged without continual recurrence to fact and observation. And among other errors, it has engendered the fancy that there were separate principles or essences of disease! But I think we may set at rest this notion, and at the same time illustrate the proper mode of embodying the fleeting elements of some maladies, by referring to our opinions concerning sleep, puberty, old age, and other modes and modifications of the human system. We talk familiarly of sleep, of puberty, of old age, in a collective sense; we observe their symptoms, their progress, their termination, their whole character; we allow that they modify the entire economy, physical and moral; but we never (except in poetry) suppose a distinct entity or essence of either. In the same way we speak of fever, of small-pox, of insanity, in the aggregate; but without considering them under the controul of an abstract power or independent principle, apart from general vitality.

Now this mode of reasoning upon *cumulative evidence*, which I have endeavoured to illustrate and ventured to inculcate, is directly the reverse of that called analysis. It may be truly designated synthesis—a placing together of parts.

There appears to be, in the minds of some persons, a strange aversion to admit a due and sufficient variety in the primary causes and intrinsic characters of diseases. The advocates of the exclusive systems of irritation or congestion, of inflammation, or of organic lesion, are not satisfied with being partial to a favourite scheme, but they must be intolerant to all rival views; and, in twisting facts to illustrate their own plans—for all parties appeal to facts—we see them continually regarding an isolated part of any composite morbid condition as if it were the whole, and installing a secondary and subordinate effect into the place of a cause. The attempts, however, to give one invariable

explanation of the most complicated diseases, and to enlist the most opposite conditions under one universal designation, are as absurd and as impracticable as would be a proposal to allow but one sense, or one passion!

In endeavouring to simplify our notions of the secret mechanism of some diseases, we lose sight of their broad and striking peculiarities. We get at the dry skeleton of pathology, without the clothing and life of clinical observation. It is no satisfactory explanation of the special differences among maladies, to learn that the nerves and blood-vessels are the universal agents in their production. What do propositions so naked, and abstract, and indiscriminating, amount to? They may be true, but they are of no avail. They are not sufficiently descriptive and circumstantial to be interesting and useful. They are like the dates and names of historical events, apart from the actions and characters of the personages. Even the terms sympathy, association of function and sensation, and other familiar abstractions, in reality explain nothing; being simply the enunciation of certain primitive facts, which are themselves to be accounted for. Inflammation, again, is a complex condition, brought about (or set up, as we say) by the simultaneous impulse of many controlling agents. In order to explain its modifications, —to understand why, in measles, it constantly prefers the Schneiderian membrane, and in scarlatina the pharynx; and is so variously directed and characterized in other diseases—we must admit the prior agency of special laws of the economy; and acknowledge inflammation to be, not a primary cause, but a morbid effect, generated by agents already in operation.

The practical views which we must take of diseases are various. We observe in cramp, and in urticaria, great pain and intolerable suffering suddenly coming on, and as suddenly subsiding. We have, on the other hand, scrofula and cancer, making of the whole of life "one long disease." We see calculus arising from some peculiar vital constitution, becoming a chemical disorder of secretion, and ending in a mechanical obstruction to healthy function. In hydrophobia we have to observe the appalling effects of an insidious imperceptible agent; and in endemic fevers, of a diffused influence, or malaria: but this malaria, or this venom, be it remembered, has never yet been detected by the most subtle mechanical or chemical contrivance. It owes its inferred existence to pure reason, or induction. At other times, the palpable cause of mischief is found to be the presence of worms, of animalcules, of biliary or stercoraceous concretions.

Plague, scurvy, cachectic maladies, and broken-down constitutions, exhibit a de-

range of many of the elements of our frame, so general that we can with difficulty fix upon any peculiar and exclusive feature; while in cataract it is merely the loss of one physical property (which is of no value but in the eye—which might never even be recognized out of the axis of vision) that destroys natural function, and leads to great consequent inconvenience. In wounds and topical injuries, it would be glaringly absurd to seek for general predispositions and distant causes of suffering, when the mischief lies before us in a tangible shape. But surely it would be quite as wrong, in many cases of hereditary malignant and contagious disorders, to overlook peculiarity of temperament and specific poisons; because the morbid lesions, which are locally developed in certain constitutional maladies, are but a small part of the whole diathesis. It not unfrequently happens, that a lurking contagion or hereditary taint, which is masked in one individual patient, or in one generation, may yet reappear in others, perfectly well-marked and developed; and we must, in such cases, consider the morbid tendency, diffused universally over the economy, or pervading certain tissues, as well as the occasional and accidental phenomena, which give an outward and visible sign of its existence. Indeed, after having gained so much in surgical matters, by advancing from the partial scrutiny of local diseases to the consideration of general physiological laws, and by mounting from effects to causes—it would be to surrender our advantage, were we, in medical researches, to retrograde and rivet our attention solely upon the traces and mechanism of disease;—this would be to mistake morbid anatomy for the entire science of pathology.

We are thus driven to recognize several established differences in the nature of maladies, both with respect to their intrinsic causes and to their aggregate character. It is difficult, and perhaps impossible, to determine with precision the proper number of classes to which all individual cases may be referred. This same difficulty exists in forming schemes of general anatomy, where writers have always disagreed as to the due number of elementary tissues: it has been found, in tracing the original varieties of the human race, and in referring particular tribes to their original source; also in analyzing the primitive faculties of the mind—about which no two metaphysicians are agreed; indeed, in all branches of natural history and throughout all science, whenever such an attempt is made, some points are universally recognized as clear and satisfactory, while there are others about which we hesitate and differ. We know that, in all vital phenomena, there is much more variation and complication than in purely physical occurrences; but yet, though our notions of dis-

ease are indefinite, and the parallel between any two cases never rigid, yet we are justified in tracing analogies between them, and in separating them into groups, and looking out for their continual reappearance, as much as we are with regard to the approximations and contrasts of colours, tastes, and musical sounds. Therefore many of the imperfect nosological schemes which have been proposed, while they have excited derision, by classing together disorders totally opposite in their nature, have at the same time been well-founded in other respects. So that, while we fairly indulge our laughter at the incongruous portions, this very impression of their absurdity allows an inference indirect, but legitimate—that there is at bottom felt to exist a foundation for a true and natural arrangement, which, if developed with skill and judgment, would be readily understood and acknowledged. Indeed it is this natural foundation of constancy and renewal in the peculiarities of diseases, which enables us to recognize, as just and faithful representations, many of the faint outlines and physiognomical sketches of maladies which our predecessors have drawn without much acquaintance with the scientific details of anatomy and physiology; and these, like many of the maxims and proverbs of remote ages, being grounded on general and imperishable truths, will always retain their value; while new illustrations, and more exquisite refinements, are continually adding to the primitive rules.

But any kind of testimony respecting the by-gone history of diseases, and shewing their identity or diversity at successive periods, is important; for “not to know (as a familiar quotation from Cicero says) what has been transacted in former times, is to remain always a child.” The information given by primitive writers, as to the appearance long ago of diseases familiar in our day, and as to the contradictory notions which have been entertained, at different epochs, concerning their nature and origin—as, for instance, about syphilis and small-pox; the accounts which we occasionally have of the varying type of epidemic maladies, of the spread of disorders considered endemic to new regions, and of the comparative fatality of plagues and pestilences in camps, gaols, hospitals, ships, and new colonies; the records of statistical medicine, which manifest the connexion between diseases and different localities, domestic habits, and political institutions;—all comprehensive reviews of this kind, tend to promote sound and just reasoning, and to keep within bounds all sanguine attempts to extend partial systems beyond their due limits; while, by accumulating facts and opinions, and by linking together individual and scattered occurrences, they enlarge and strengthen the basis upon which our practical conclusions

rest; and give a stability to the whole fabric of pathology, which in its subdivisions cannot be obtained.

In this way medicine rises, from being a conjectural art, to rank on a level with the more determinate sciences; the particulars being indefinite and varying, the general results regular and constant.

But however interesting the study of diseases might be, as a branch of natural history, and however necessary to the proper appreciation and discrimination of such preternatural conditions we might consider the cultivation of morbid anatomy; yet this portion of our professional studies would never have attained to the rank which it holds in the estimation of the candid and enlightened, were it not for the intimate relation between pathology and therapeutics.

Enough has been said already of a disposition to continuance in pathological notions, notwithstanding occasional fluctuations in opinion, and partial improvements in research; and I could quote very good authority to tell you that, in therapeutics, there has been still greater constancy and adherence to ancient methods; but, upon reflection, I am myself disposed to think differently. Nothing, indeed, could be made to appear more contradictory and inexplicable than an exposition of the countless multitude of remedies which have at different periods risen into esteem, become widely employed, and have then been forgotten; but it would be a fruitless, and indeed melancholy task, to marshal in opposition the hosts of absurd theories and ignorant practices—to compare their rival uselessness, and determine their precedence in folly. It will better suit the purposes of this investigation to mark the constant parallel which has existed in the progressive development and improvement of systematic and practical medicine. Remedies have been for ages proposed for mere symptoms, without an attempt even to remove the intrinsic causes of disease; and have been supposed to act with a peculiar and specific force upon morbid phenomena; which scientific investigation has discovered to be mere ingredients in the sum of a composite disorder;—and this short-sighted and superficial treatment has prevailed in internal as well as in external maladies. On the other hand, and contrasted with this fault, we find a corresponding rage for simplicity. There have been as many sweeping and uncompromising schemes in practice as in theory; and in the same way these are always fabricated by forgetting causes, confounding opposite conditions, and overlooking indications of cure held out to us in many characteristic ways.

But it is not as companions in error and humiliation alone that theory and experiment have been joined: the same light which has been shed upon anatomical, physiological,

and pathological researches, has reflected its influence upon therapeutics; and, in a great share of morbid conditions, the *methodus medendi* has been rendered more clear, and the cure more certain.

Within the department of the physician, the relation between the natural or modified functions of the various tissues and organs, and the curability of disease, has been successfully investigated and very generally acted upon. In surgery and in midwifery, the connexion between scientific knowledge and remedial power has been still more direct and available. But from no part of our profession is the mortifying but just opprobrium removed—that, on too many occasions, our researches serve, indeed, to shew us the character and progress of malady, but do not, in an equal degree, disclose the means for its prevention and cure.

The continual reaction of experiment upon theory, and the intimate relation between pathology and therapeutics, being then recognized, and their co-operation both for good and evil illustrated, we can explain the influence of rational and enlightened medicine, founded upon anatomy and physiology, in hastening the downfall of many specifics, and in putting out of fashion many long-established remedial agents.

We know that one of the avowed objects of medical surgery is to diminish the number of operations, and to simplify cumbrous apparatus and complicated manipulations; and there is no question that, throughout the healing art, the habit of tracing the natural history and tendency, and termination of diseases, goes to weaken our reliance upon numerous medicaments which have been in their day held in wondrous estimation. A trivial acquaintance even with morbid anatomy will induce us to relinquish, in certain cases of organic lesion, all expectation of restoring original structure. Habit and prejudice may, however, so long associate the administration of certain drugs, or the employment of certain instruments, with familiar diseases, that their disuse shall come to be regarded, by the ignorant and bigotted, as a surrender of power and a neglect of opportunity. But by those who are sufficiently used to weigh the force of physiological laws and pathological conditions, against the transient and trifling effort of superficial and misdirected plans of cure, it will not be allowed that any really useful agent, or any strictly necessary operation, was ever banished from the medical commonwealth. When our researches lead us to refer certain painful affections to the trunks of nerves, or to their origin in the brain or spinal cord, we are not guilty of neglect in slighting many popular applications to their sentient extremities. If we treat with contempt a variety of cordials and nervous medicines (which both experience and science have proved to

be inefficient), we are not thereby discountenancing any cure for organic obstructions to the circulating apparatus; nor do we, in forgetting to employ various mucilages and gums (which could at best but coat the surface of the mucous membranes), abandon any effectual cure for tubercular phthisis.

Many of the erroneous notions which have prevailed, concerning the power of remedies and the necessity for operations, have grown up from the popular custom of attaching importance to the drug or to the remedial agent, without regarding the variously combined circumstances which call for its employment; and the same error has pervaded many fixed plans of diet. Every day, however, teaches us the folly of imputing a virtue to the means of cure independent of the inherent capacity of the vital condition to turn it to account; every day teaches us to expect nothing from the seed, when the soil is not fitted to receive it. But here a reflection arises, as to the due extent of our allegiance to philosophical or scientific schemes of practice. Some doubt may be very justly entertained, even by those who are the most anxious to extend the dominion of reason and logical induction, whether the habit of adapting means to ends, and of calculating results from established analogies, may not beget a disposition to scruple the employment of what is useful, merely because its mode of operation is not clear, and to strain after an explanation on occasions, when it cannot, in the nature of things, be obtained, and we must be content simply to observe events; whether we are not apt to forget that the immediate and specific action of all remedies upon our organs is a thing of fact, and not of reason and contrivance?

Experimental medicine, the most ancient, and, all things considered, the most extensive division of our art, is the common ground where men of all opinions and all degrees of acquirement, must at times meet. And it is mortifying to one who has spent his life in scientific research, and grown old in the upright and rational use of professional experience, to be occasionally put on the same level with the youngest practitioner, and jostled indiscriminately by quacks. However, most things in this world have sprung, not from science, but necessity. If, indeed, one consider how few remedies, even the most familiar, act intelligibly and directly, and how many may be resolved into distant counter-irritants and fancied contra-stimulants, that they all transmit their power through a medium which is not the passive and faithful recipient of impressions, but is frequently active in defeating or modifying their influence,—if one scrutinize very closely the shifting and contradictory results of most experiments made upon vital organs, and be not content to receive as a satisfactory explanation what he frequently

suspects to be merely a coincidence of unconnected facts, such a one will not wonder at the occasional disappointments to which the most experienced are at times subjected, or at the disparity of benefit arising from the best-advised efforts.

Yet, with every allowance for the uncertainty in which remedial agency must ever be involved, and with every wish to encourage the extension of free and unshackled inquiry, we may with perfect fairness decide, that, even in those cases where the ultimate appeal is made to experiment, much may be done by scientific investigation and judicious preparation, towards narrowing the field of operation, and selecting a propitious moment for trial. Without alluding to the more established professional means of cure, this position could be exemplified by the production of innumerable examples, in which the rational employment of *specifics* even would be contrasted with their indiscriminate administration. But I will take as a mere illustration what we hear of the *ergot of rye*. If the reputation of this new therapeutic agent be well founded, and the testimony of many practical men in its favour be received, it would appear to be gifted with a peculiar, unexplained, and *specific* power over the uterus, which renders it, without any insight at all into its *modus operandi*, of the highest utility in the hands of the skilful, under a certain combination of circumstances, and controlled by the presiding influence of prudence and integrity; but when not used, but abused, by those who are unacquainted with physiological and pathological conditions, ignorant of anatomy, and untaught by clinical experience—who have neither the subdued and practical intelligence, nor the scrupulous fidelity of the true physician, is liable to become a pernicious and destructive instrument.

As to the popular reproaches which have been so frequently cast upon the more *orthodox* of our class, concerning jealousy of innovators, and unwillingness to adopt efficient remedies merely because they did not enjoy the sanction of authority, these are daily becoming more inapplicable. Indeed, the ready and universal promulgation of vaccination by the educated and enlightened, in opposition to the most inveterate prejudices of the vulgar, would alone be sufficient to repel from our profession the charge of undue adherence to antiquated notions. Perhaps we may go further, and say, that in our day, the sin of bigotry and partiality lies really at the door of the empirical practitioners, who are commonly attached with blind and engrossing confidence to a single system or mode of cure, and prove on acquaintance to be, as it is called, “people of one idea,” which they are eternally pursuing, and investing with false and exaggerated

airs of importance. How many quacks would go to the composition of an accomplished eclectic practitioner, I have never attempted to calculate. But it appears certain that we are less scrupulous about the source of knowledge or power, than about its practical value. Indeed, the liberality of the profession with regard to new remedies, very much approaches the easy carelessness of the polytheists of the Augustan age on the score of new religions. We have, like them, our old and tried modes—our household gods; but as these are not all-powerful, we are very ready to enlist the divinities of all other countries into our calendar, and go where we may, to exchange our forms for others which may prove more efficacious. It is true that the miraculous pretensions of certain idols, which some enthusiasts have called upon us to worship, have at times been treated rather unceremoniously; this disrespect has, however, been excited not by their novelty, but by their impotence!

But after all is considered that reason can suggest, or that quackery dare risk in the way of relief to suffering, there remains a large proportion of cases where we are equally deserted by theory, and compelled to relinquish experiment, which innumerable trials in analogous examples have proved to be of no avail; where neither science nor experience uphold us, and we drop into the Dead Sea of expectant medicine. This dull and sluggish element, which has engulfed so many sanguine schemes, is looked upon with a natural feeling of dislike by the ardent and enthusiastic; and yet, in too many instances, “to this conclusion we must come at last.” However, I shall endeavour to shew that there are considerations which may reconcile us to the occasional submission of our aspiring endeavours unto the irresistible sway of natural laws; at any rate, I shall satisfy you that in making a necessary concession, it is more agreeable to be led by reason than driven by despair.

There is this great distinction to be made by those who practise faithfully, which, without being definite and exact, is sufficiently broad and intelligible to warrant us in paying it attention. In many cases of malady, the system may be regarded as the recipient of morbid impressions from some external agent, or is passive under the infliction of an injury which is accidental and extraneous; or, at any rate, the constitutional disturbance which may arise is rather a reaction or consequence of the original impulse; while in the generation of other diseases the intrinsic elements of the frame seem spontaneously active; these are set up and developed in a manner allied to the natural revolutions of the animal economy. The former class, or accidental complaints, may be com-

pared to the invasions of a state by a foreign foe, which are irregular and unexpected occurrences; while constitutional diseases are like civil tumults, depending upon latent causes, and proceeding as a necessary consequence of the growth and progress of a nation, and partaking of the popular condition and character. We know these last to be so entirely concomitant with the established functions and natural changes of the system, that they can only be understood by constant reference to primary physiological laws. We find a gradation from varieties of race and temperament, differences of constitution, diathesis, idiosyncrasy, habitual mode of life, and prevailing passion, or bent of mind, till there is but a step to actual disease. And then maladies are grouped according to different ages and functional periods, as the disorders of infancy and dentition, of childhood, puberty, of gestation, and the change of life in females, and, in both sexes, of old age; there are, in short, so many links between intrinsic or constitutional complaints, and the unavoidable events of our physical and moral existence, that they can never be properly contemplated apart.

Now granting that much may be done by scientific measures, and even by empiricism, in accidental diseases and injuries, we must conclude that there are others where all abrupt interference with spontaneous natural processes is equally forbidden by reason and experience. But if there remain in the breast of any a feeling of dissatisfaction that on so many occasions we are compelled to caution and inactivity—that the character of philosophical medicine is so frequently negative, we may remind them that our profession is part of human nature, and must consequently ever partake intimately of its obscurity, uncertainty, and littleness. “It must be remembered,” says Dr. Johnson, “that life consists not of a series of illustrious actions or elegant enjoyments; the greater part of our time passes in compliance with necessities, in the performance of daily duties, in the removal of small inconveniences, in the procurement of petty pleasures; and we are well or ill at ease, as the main stream of life glides on smoothly, or is ruffled by small obstacles and frequent interruptions.” Reflecting on this, educated men of good sense and integrity will not lend themselves to the plans of extravagant pretension and ignorant meddling, by which quacks exist. Indeed we know, from what goes on in the world, that the only persons who engage to cure all diseases, are precisely those who know least about them. But while conscientious practitioners lay no claim to such unlawful and spurious titles to consideration, they have an ample inheritance of usefulness in the wide field of pro-

phylactic, dietetic, and palliative medicine. In no way have we added more to our true power than by relinquishing violent and ill-advised practices, in favour of modes of cure “by the first intention,” as it is called, and by the skilful management of general physical agents and moral influences, which “do good by stealth.” The information which is daily pouring in upon us, as to the secret but sure operation of climate, of habitual mode of life, of social and political circumstances, and of the change of these circumstances upon individuals and communities; the close alliance which is continually forming between our profession and the many sciences and useful arts which illustrate the nature of man, develop his faculties, improve his condition, or mitigate his sufferings;—all combine to gain for us sure and legitimate advantages, and to extend the beneficent influence of sober reason.

I have endeavoured, in this imperfect outline, to point out the existence in medicine of two great conflicting principles—one of analogy and constancy in aggregate events, and one of infinite variety and fluctuation in details; and to illustrate the necessity for those technical fictions by which they are reconciled. I have attempted to illustrate the analytical and the synthetical modes of appreciating disease, and have considered that general arrangements and descriptions forward us, while universal indiscriminating schemes carry us back to the original chaos; that the importance of morbid anatomy, as an auxiliary study, is too generally acknowledged to require argument; but that, while its cultivation, associated with physiology and pathology, is obviously necessary to the elucidation of some diseases, it is, when proposed as a rigid test of others, not only insufficient in point of fact, but unphilosophical in its aim; because no localization can be attempted of those maladies which are diffused, and because no single method of investigation can embrace all the elements and relations of the more complex disorders.

I have concluded that our profession, moving forward with the general impulse of the age, shews a disposition to turn every science and every system to practical account, yet rebels against all attempts to enslave it to any one in particular; but that, having learnt caution from the past, it advances, by the aid of present intelligence, to unlimited discovery and improvement—*Nil actum reputans dum quid superesset agendum.*

ON SEVERAL AFFECTIONS OF THE
LARGE INTESTINE.

BY PHILAETHES.

No. II.

*To the Editor of the London Medical
Gazette.*

SIR,

In the present paper I purpose describing, in a very cursory manner, several affections of the large intestine. These are, 1. *Inflammation of the appendix vermiformis cæci, from calculus in that organ, with its fatal consequences.* 2. *Inflammation seated in the region of the sigmoid flexure of the colon, with symptoms of stricture, and its cure by mercury.* 3. *Symptoms of stricture of the rectum, leading to the erroneous and injurious use of the bougie;* 4. *and lastly, an affection of the bowels, arising from thread, or the fibrous and indigestible parts of vegetables, inadvertently swallowed.*

I. Several years ago I was consulted by an anxious father in the case of his son, a little boy, about 12 years of age. He had suffered for some days from pain seated in the region of the appendix vermiformis cæci. He had been bled from the arm, and leeches had been applied, but in vain. He seemed to bear the loss of blood very ill. On examination I found a distinct tumor, exceedingly tender on pressure. The pulse was frequent; there was much complaint of delirium. These symptoms continued, and the little patient sank rather rapidly.

On examination after death, coagulable lymph was found poured out over the surface of the hollow of the left ilium, and the appendix vermiformis cæci was seen to be enlarged and charged with blood of a venous hue. On opening this organ, a concretion was discovered embedded on its narrow canal; and on further examination, the nucleus of this concretion was found to be a small plumb-stone.

In another case, of a precisely similar character, the nucleus was a common pin; and in a case published many years ago (I believe by Dr. Briggs, of Liverpool), in the Medical and Surgical Journal of Edinburgh, the nucleus was a tooth, which the patient had doubtless

swallowed on its becoming loose and detached from its socket.

I should add to these remarks, that a similar case was attended recently by Dr. Stephen Hall, of Walworth, who was so kind as to present me with the concretion; and for a chemical examination of it I am indebted to Dr. Prout. That gentleman observes, "the concretion you were kind enough to send me, consists essentially of the phosphate of lime and a little carbonate of lime, united with a considerable proportion of animal matter, partly of an oily nature."

I fear the only point we can propose to investigate in this disease, is its diagnosis, and the consequent prognosis; with the additional advantage of being preserved from the employment of useless and improper remedies. These, however, are points of no mean consideration in the practice of physic.

II. The second case of disease which I proceed to bring before your readers, is one of a very different character, inasmuch as its early detection leads to an efficacious mode of cure.

Some time ago I was consulted in the case of a young married lady, at Pentonville. She had long complained of pain situated over the region of the sigmoid flexure of the colon, increased on pressure, and on taking purgative medicine, with great difficulty in moving the bowels; in short, of all the symptoms of partial stricture.

I prescribed the unguentum hydrargyri, so as to affect the mouth. The symptoms slowly, and eventually, and entirely disappeared.

Shortly after this period, I attended a servant maid, residing at Paddington, affected by similar symptoms, of considerable duration. There was great tenderness under pressure; the action of all aperient medicine was painful and difficult. The symptoms were longer in yielding; the mouth became very sore; but the symptoms did yield, and the patient, after having been for a time in the country, is once more in good health, and occupying her former situation.

I have considered these cases as instances of partial peritonitis; and for the use of the mercury as a cure for this disease, I believe we are indebted to Dr. Farre, to whose useful labours in our profession it gives me great

pleasure thus to add my feeble but sincere tribute of praise. To this gentleman's useful discovery, a poor woman, affected with tumor from partial peritonitis, occurring after delivery, owes her recent restoration to her family: but it would be foreign to the objects of this paper to detail a case, however interesting, here.

III. I now proceed to the third subject of this essay. It occasionally happens that symptoms resembling those of stricture of the rectum occur independently of that formidable disease. Such a case fell under my notice some years ago. It may offer a useful warning to the young, and to those whose minds may be biassed (and whose is not?), to detail it here.

The patient was a medical practitioner. Naturally, or at least during a long time, pale, he became paler, thin, and weak, and was obliged to relinquish the toils of a country practice. After a time he went to Bath, unimproved in health. He there met with a gentleman, who took up the idea that the case was stricture of the rectum. (I believe such phantoms have much haunted that region of late!) It was but one step farther to the use of the bougie. This remedy was therefore employed daily, during the remaining part of this patient's residence at Bath.

On quitting Bath, I met my friend in London. We consulted Dr. Mansfield Clark. He concurred with me, that there was no stricture. The bougie was relinquished, and the patient recovered forthwith!

It may be said that, in spite of what has been narrated, there still was stricture. To this allegation it may be replied, first, that during nine weeks' daily attendance *before* the visit to Bath, I could detect none; secondly, that immediately afterwards, Dr. Clark declared that there was no disease—an opinion, the truth of which the event has proved; thirdly, it must at least be admitted, that were the bougie *ever* required, it was at least continued too long; and fourthly and lastly, that the stricture, if it did exist, was not scirrhus.

I leave these facts and remarks with your readers. I warn them to beware of a bias so apt to creep into the minds of medical men, leading them to conclude too soon that the case is so and so. Let us listen more to our patients,

and reconsider their cases; and we shall become better, because, in the best sense of the words, more cautious, practitioners. Another case precisely similar occurred to me in the person of a lady of Lincolnshire a short time ago. The bowels could not be moved; the case was judged to be stricture; the bougie was employed! yet there was no stricture!

IV. A short time ago I received from a lady, residing at Bayswater, a vial containing much stringy, fibrous matter. It had been passed by her little boy, about seven years old; without, however, having induced any symptoms.

I examined this substance carefully, but could not discover what it was. I sent it to a well-known chemist, who gave it as his opinion that it was of vegetable origin, and suggested that it might be the fibrous part of rhubarb, or of French beans; and stated that he had known distressing symptoms to arise in the case of a woman who was in the habit, in sewing, of swallowing ends of threads;—these had formed into balls, had induced inconvenience in their transit through the alimentary canal, had been passed, and had been afterwards unravelled.

The case of my little patient occurred, however, in the month of September, and the mother of the little boy could offer no conjecture as to the source of this fibrous substance, even after its supposed origin had been suggested to her. Might it be the fibres of liquorice-root? It was afterwards conjectured that it was the fibrous part of radishes taken up at this untimely season of the year.

Nothing would be more useful, in medical literature, than *complete tables* of all such morbid affections as have been *known* to exist. So many are overlooked, merely because we are not aware of their occurrence in practice, if this happen to be rather rare, that such tables would form an important clinical companion. But more of this hereafter.

I remain, sir,
Very sincerely yours,

PHILAETHES.

OBSERVATIONS

ON

MR. BARTON'S MODE OF TREATING
CERTAIN INJURIES OF THE EYE,

By R. MIDDLEMORE, Esq.

Assistant-Surgeon to the Birmingham Eye
Infirmary.

— —

BEING connected with a large institution for the reception of patients affected with "diseases of the eye," situated in the midst of a manufacturing and mining district, it may fairly be presumed that an immense number of accidents similar to those mentioned by your correspondent at Manchester present themselves to my notice.

When a patient has received a punctured wound of the cornea and capsule of the lens, I should not content myself with "promoting or subduing inflammation by venesection, leeching," &c.; but after having prevented, as far as possible, the occurrence of severe inflammation, by bleeding, counter-irritation, and cooling lotions, endeavour to promote the speedy absorption of the lens, and prevent the contraction of the pupil, by calomel and opium, and the local application of belladonna cerate. Should this accident occur in a young person (the iris not being wounded, and the section of the cornea being small), I should expect to accomplish these objects with tolerable certainty, without having to encounter any such symptoms as continued pain and disorganizing inflammation of the iris, from the pressure of a soft and broken lens; or meeting with, "in the majority of cases," the catalogue of evils enumerated by Mr. Barton. In a patient more advanced in life, with a hard and large lens, fixed in a situation intermediate between the anterior and posterior chambers, its sharp edges resting against the pupillary margin of the iris (a singularly rare phenomenon), symptoms of a severe character, justifying the immediate removal of the lens, may arise; consisting chiefly of intense pain, commencing change of structure, and irritation of the opposite organ. I however repeat, that it is not customary for a lens, not altered by any morbid action, to produce any very severe and uncontrollable symptoms, when situated in the anterior chamber—the iris,

in such case, not being pressed against a hard and unyielding substance, but floating, though not so freely as usual, in the natural secretions of the part. In proof of this opinion, I would refer to the case of spontaneous dislocation of the lens, shewn to me by Mr. Smith, to which I have alluded in my report to the Midland Medical and Surgical Reporter.

During the last year I have removed from one patient a long lens; from another a morbidly enlarged and dense lens; from a third a large mass of thick lymph; which in each case, by its pressure upon the iris, produced symptoms of a most tormenting and unmanageable character; but in no case has it been found necessary to remove a natural lens when displaced either by wound of its capsule, or from concussion. A blow upon the eye, or severe concussion of the body, more particularly a fall upon the head, is sometimes succeeded by displacement of the lens. Inflammation, in its severest form, arises as a consequence of so great an injury: to attempt to subdue inflammation so excited by the infliction of additional injury, would, in my humble opinion, be a measure opposed to all sound and judicious practice. Did the inflammation arise from the pressure, and not from the concussion or the blow, the extraction knife, it is admitted, would be the best remedy for its cure.

I believe, sir, that in most instances where it becomes necessary to remove the crystalline lens, in consequence of its injurious pressure upon the iris, the dislocation has been occasioned by disease—the lens being, for the most part, changed in figure, structure, or consistence; the various textures of the eye being irritable and morbidly sensitive, and the absorbing surface of the chambers being, by some process or other, destroyed, or prevented from acting in a sufficiently energetic manner to remove the irritating substance. There can be, therefore, no prospect of its absorption; and its removal can only be accomplished by an operation.

In conclusion I would observe, that whenever a lens has become dislocated by accident, and does not appear to be acted upon by the absorbents, after a proper plan for the removal of inflammation and the promotion of absorption has been adopted—if the pain and inflammation continue—if change of struc-

ture commence, and the opposite organ become irritable and painful, it ought to be removed, and extraction is, of course, the proper operation for that purpose; but to remove it by an operation capable of inflicting much injury, and producing great inflammation, before these measures have been employed, would, in my opinion, be a needlessly precipitate and injurious measure.

MEDICAL GAZETTE.

Saturday, April 3, 1830.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."—CICERO.

UNIVERSITY OF DUBLIN.

WE have recently perused, in the pages of our weekly cotemporary, a leading article under the very attractive title of the "Dublin Mother and her Babes;" consisting of an imaginative essay on the ordinances of the Irish University. We read the article with due attention, and will take leave to offer a few remarks on its merits. But first we must confess, that though in some measure prepared for the perusal of this rare diatribe against the medical school of Dublin, by the preliminary flourishing of the writer in some two or three preceding numbers; yet, from the spiritless, soporific quality of these, we thought it more than probable that the gentleman would, in the end, lull himself and his readers into a perfect sleep: he has, however, at length roused himself up, though the illusive character of his sleeping thoughts is still evidently impressed upon his waking deliberations; the phantoms of the ivory gate are still pursuing him; and the consequence is, his present incubration has all the extravagancy of a waking dream. It is, in truth, a most rare composition. An eminent authority has told us, that there has never yet

been a tissue of falsehood so complete and perfect, as not to contain at least some truth in it. We are tempted to pronounce the article on the University of Dublin an exception; for, from beginning to end, we cannot find a single statement that is not utterly untrue. If the writer was really broad awake when he penned the precious document, we cannot help wondering where he thought the intellects and the judgment of his readers, however humble, were fled, when he ventured to dose them with such assertions. The credit he gives them for gullibility is surely unlimited; as for common decency, it is a thing of no account—a superfluity not regarded by the writers, and therefore apparently not much prized by the readers of the *Lancet*. We will therefore pass over, as matter of course, the vulgar strain of indecent imagery in which the article in question is couched, and proceed at once to notice some of its most material falsehoods; premising that Ireland is not quite at the Antipodes, that the truth should be ascertained with difficulty. *Sus minervam* is an adage in point, and sufficiently descriptive of the rank and consequence of this literary reformer; but lest there should be any weak enough to credit his statements, or to countenance his pretensions, we shall exhibit a sample of his quality, and shame him by a simple test—if he be not indeed proof against that charm which could shame the only one we ever heard of who was a greater falsifier than him.

It would be ridiculous to enter upon a defence of the medical arrangements of the University of Dublin, by way of answer to any remarks coming from such a quarter; much more to complain of the abuse which the writer endeavours to heap on the discipline in arts afforded by that seat of learning. His flippant mis-statements (too gentle a name to give them) abundantly shew

the extent of his acquaintance with either the one subject or the other. When we find him talking of "putting in our terms," in a university where *no degree* is obtained by keeping terms; of the "absurdity of a four years' classical noviciate," as descriptive of the undergraduate course in a university which emulates the discipline and attainments of her learned sister of Cambridge; of certain regulations of costume, which could only attract the notice of little minds, as "ordinances" of the Irish University; we have some clue to what *he* knows about taking a degree there or any where else. When we have Sir Oracle delivering himself on the reading and study suited to an accomplished physician, and declaring, *totidem verbis*, that "the classical part of the matter might be entirely dispensed with," we may safely allow him to proceed in this matter as he has begun—with his harmless and puerile absurdities.

But if from these we turn to his medical strictures, we shall scarcely find that he is one whit more wise or better informed. On the arrangements of the University of Dublin with respect to graduation, he had probably been told by some one that there were two kinds of medical degrees obtainable there—one in three years after the preparatory and indispensable degree in arts, the other in five years after the first medical degree. The same arrangement prevails in the other faculties of common law and divinity; the first degree being *ad respondendum questioni*—the second, and final one, *ad incipiendum*. Every university man must be familiar with this. Yet the detail, it seems, was too complicated and puzzling for the editorial scribe of the *Lancet*. The University of Dublin, he immediately informs his readers, turns out two sorts of practitioners, each with a license to practise; which, he humbly conceives, is both inconsistent and cri-

minial. Here there happens to be only a double blunder; for the University not only gives no license to practise, but never once recognizes her graduates as practitioners. The same ordinance prevails at Oxford and Cambridge, and forms a striking contrast with the manner of proceeding in the universities of Scotland.

That the gentleman is so well satisfied with the doctors graduate, must be a pleasing reflection to them: he complains, indeed, that they are twelve year men (though, with a curious confusion of ideas, he describes them as old practitioners at the end of this period), but, on the whole, he is evidently very well content with them. The doctor graduate is quite "a master-piece," in his opinion; the only "genuine" doctor—a scholar and a man of experience—and every way a very "superior" personage; one on whom "the old lady" has expended all her care, and in whose nourishment she has taken especial pains. Now what are the facts? This "variety" receives *no education* from "the old lady," beyond what he obtains as a bachelor of medicine; he is simply a bachelor of at least five years' standing, and undergoes, in general, *no examination* for his degree—or if he do, merely a formal one; more especially if he have been previously examined by the same professors for his bachelorship. So that all the statement about "her reserving all her amiable severity for her final scrutiny into his deserts, when conferring on him her last rewards," is perfectly gratuitous and false.

But if the gentleman be so well satisfied with the education of the "genuine" doctor—who, by the by, is truly a *rara avis*, there being perhaps not five of that class in all Ireland (nay, perhaps not half a dozen have commenced there as full doctors of medicine these twenty years,—he must be also satis-

fied—though he will not confess it—with the education of the bachelor; for his *alma mater* takes, as we have already intimated, no cognizance of him after his first medical degree—knows not, in fact, that there is such a person alive, until he comes to look for his last honours; she then ascertains that he has duly obtained his bachelorship, and that the proper interval has meantime elapsed. Thus the bachelor of physic is ultimately dubbed a “genuine” doctor. We will now go farther, and shew, that though there is no such thing as an eight years medical education in the University of Dublin, the three years noviciate is of such a nature as to enable the Dublin bachelor of physic to take his stand with any graduate doctors of his own or any other university in the united kingdom.

To obtain the bachelorship of medicine in Dublin, the admirable course laid down for all students in arts in that University must be previously gone through; and the first degree in arts cannot be obtained in less than four years and a half. With this preparation, the student is supposed to enter upon his medical career with peculiar advantages; and so he does. It should not be omitted that this preparatory course, in addition to an ample and wide range of classical literature, embraces also an extensive field of pure and mixed mathematics—the latter fully illustrated by the sciences of astronomy, mechanics, hydrostatics, and optics; the other parts of the course take in metaphysical and moral science. We take for granted, that it is not necessary to prove by example how well calculated this course is to form the habits of the student, and to enable him to adorn his profession and walk in life, whatever they may be. Eminent individuals, educated in the Irish University, will readily occur to the memory of every reader. They have lived many of

them, to shed a lustre on the historical records of their country; they shine, and have shone in the senate; and they constitute a great body of the most popular writers for the British press. So much for the senseless sneers of the writer in question, who is incapable of appreciating what he has never enjoyed, and cannot understand. But to return to the medical arrangements. After graduating in arts, the student enters upon a three years’ course of medical study; he may, indeed, have attended some of the medical classes simultaneously with his studies in the arts; and frequently this is the case, though it does not reckon in procuring him the bachelorship the sooner. The course of medical study is precisely similar to that prescribed in Edinburgh; the requisite attendances on professors are the same for the Dublin bachelor and the Edinburgh doctor; while the former has this peculiar advantage superadded—that he has been previously initiated in the arts; and it is scarcely necessary to allude to his superior opportunities in pursuing his anatomical studies in the sister kingdom. No doubt there may have been many who have squandered away their opportunities and advantages—who have contrived to cheat their *alma mater*, and have procured admission to a rank and station of which they are unworthy. These are evidently “the stuff” with which the writer in question boasts an intimate acquaintance.

We shall now briefly shew cause why the bachelor of physic in the Dublin University may justly consider his *academic* education as complete; and why he may very properly (notwithstanding the negative of his learned adversary) “arrogate the titles and habits of the genuine doctor.” He has good and potent reasons for so doing. In the first place, his expenses of time and money, in attaining the bachelor-

ship, have been so considerable, that prudence naturally suggests to him the propriety of thinking twice before he expend another heavy fee, and wait five more years for the *summi honores*—a mere title, as I have already explained. Again: the education he has been already provided with, is as good as he could have procured in any school in the British empire. And, lastly, the education of the bachelor of medicine is the entire of the medical education which the University affords; no solid or essential benefit is derived from his longer residence. The Dublin bachelor, therefore (unless he have some very unusual motive to influence him), feels himself competent to enter upon his professional career without further delay; and if the courtesy of the age style him “doctor,” as it does the bachelors of Oxford and Cambridge, he would be a fool to reject the denomination, while he is sensible that he has so good a right to the distinction.

Enough has been said, we should think, to expose the unfounded and presumptuous assertions of this writer; though we have touched on a few only of his manifold misrepresentations—to discuss them all would require the space of a whole Gazette at least. The gross and clumsy fiction of a “twelve-year variety,”—the “genuine” doctor, who receives eight years’ medical education, of a peculiar and recondite character—is entirely the offspring of the writer’s brain—a man of straw, whom he erects into a goodly and respectable shape, for the mere purpose of making an exhibition of him. His account of the bachelor’s noviciate, as of inferior description, or defective, is not supported by the shadow of a proof, and displays an utter ignorance of the Dublin University as a school of literature and science. Why should we, then, be surprised at such egregious nonsense as the following, by way of upshot to his re-

veries? “We conceive,” says the editorial functionary, “that eight years are too much, and that three years are too little, for acquiring a competent knowledge of the medical sciences, and that the classical part of the matter might be entirely dispensed with.” Eight years too much to spend in acquiring a competent knowledge of medicine! Shades of Sydenham, Mead, William Hunter, and Baillie, hear it not! though the novelty of such a dictum, did it proceed from a quarter more respectable, were enough to startle you from your meditations in Elysium. So, it seems, whenever eight years are devoted to the study of medicine, there is a certain loss of time; a competent knowledge (competent for what?) is better had in four or five. The prevailing opinion among those who might be expected to know better, is, that the labour of a man’s life, and of a long life too, is inconsiderable in respect to the boundless extent of medical science. Our reformer, however, is quite of another mind; though, according to him, we may have a “genuine” doctor—“a master-piece”—quite a “superior” personage, after an eight years’ education; yet, forsooth, again eight years are “too much.” But enough; we treat the silly trash too respectfully in bestowing so much notice upon it.

To conclude: whilst we would vindicate the system of medical education in Dublin from the slanderous aspersions of the *Lancet*, we are far from holding it up as a model of perfection. Much, no doubt, might be pointed out in it susceptible of improvement. Neither should we hesitate to pronounce that improvement will in due time be adopted; but, of course, with a prudent circumspection, as it should always be in a matter of so much importance, and of such difficult discernment. But whenever any change may occur, the sophism of *propter* for *post* will im-

mediately come into play; it will be entirely owing to the ordinances of the *Lancet*. It is quite ludicrous to observe the pretensions of the "invaluable" editor in this way. He predicts with all the talent of another Partridge. Wait till "the ensuing autumn," has been repeated till the phrase was in men's mouths as a jest; an eclipse of the moon is to occur on a certain day, or a certain great event will take place in a certain great and learned body within the year: the matter may occur in the ordinary course of things, and it is pointed out vauntingly by our learned friend;—that was *my* thunder, he says, like poor philosopher Dennis. In this way he lately boasted of certain regulations in the new charter of the College of Surgeons in Ireland; and now he predicts a reform which is "to take place at some future day," in the University of Dublin. Well may he exclaim, "O bone, quicquid dicam aut erit aut non."

LIBRARIAN TO THE KING.

THE late Dr. Gooch was the first member of our profession who held the office of Librarian to the King. The vacancy occasioned by his death has just been filled up by the appointment of Dr. Macmichael; and we have pleasure in mentioning the nomination of that gentleman, both because an honourable mark of distinction is thus retained in the profession, and because it is bestowed on one whose accomplishments and character entitle him to the respect and esteem of his brethren.

SLANDEROUS ATTACK ON MR. BENNETT.

AN *anonymous* attack on Mr. Bennett, charging him with dereliction of his duty as a teacher in the London University, appeared in the *Magazine of Slander* the week before last. A meeting was immediately held by his pupils, and certain resolutions of rather a pithy

nature passed; in which these gentlemen state, that they "view with *disgust and indignation* the unfeeling and ungenerous allusion made by the writer to Mr. Bennett's late severe indisposition," and that they "feel an *unlimited contempt for the dastardly manner in which this attack has been made*;" that they "feel perfectly satisfied with the arrangements which Mr. Bennett has made," and "consider the charge of neglect against Mr. Phillip *a gross falsehood*." This document, signed by 110 pupils, was transmitted to the Editor of the *Lancet*, who was thus compelled to record the malignity and falsehood of the charges which had appeared in his previous number.

VACCINATION.

Copy of the Report from the National Vaccine Establishment to the Secretary of State for the Home Department. Ordered to be printed March 11th, 1850.

TO THE RIGHT HON. ROBERT PEEL,
Secretary of State, &c. &c. &c.

SIR,

WE have the honour to inform you, that the small-pox has prevailed epidemically in several parts of the country, with great severity, in the course of the last twelve months, and that not less than twenty-eight well authenticated instances have been reported to us, from different parts of the kingdom, of the disease having recurred to people who had had it before, either naturally or by inoculation.

We cannot be surprised, therefore, if it shall have been found that many who have been vaccinated, have also contracted the small-pox after it.

We have the satisfaction, however, of being assured, on the most unquestionable authority, that vaccination has protected some individuals under the most dangerous exposure to contagion, and that those who have been so unfortunate as to take the small-pox after it, have very generally passed through a mild and safe disease.

We are not disposed to over-rate the value of the resource, the administration of which you confide to our super-

intendence, by considering it as affording a certain security against small-pox in all cases ; but every year places its comparative merit in a more striking point of view ; and we persevere in declaring, that we believe it to be as much more prudent to vaccinate than to inoculate, as it was better to inoculate than to allow the small-pox to take its course without control.

Signed by the usual Officers.

COLLEGE OF PHYSICIANS,

Monday, March 22.

SIR H. HALFORD, PRESIDENT, IN THE CHAIR.

THE meeting this evening was perhaps the most crowded of the season, and we observed in the room many unprofessional persons of rank and literary distinction. Dr. Hawkins proceeded to read a paper, by Dr. James Wilson, on

Apoplexy of the Lungs, with thickened Mitral Valves.

The author began by stating that there exist relations between the heart and lungs, both as to structure and function, which are too little observed. The action of the heart, he remarked, is considered too simply ;—the single fact of the circulation, deserving as it is of admiration, becomes still more so when contemplated in its details and various contingencies. To some of these, as connected with certain changes of structure in that organ, it was the author's wish to direct the attention of his hearers.

These diseases have of late been so much investigated, and have been so much in fashion, that it has been supposed by some that structural derangements of the heart are actually more common than formerly—a circumstance attempted to be accounted for by the increase of moral and physical causes in this sensitive age acting sympathetically upon the heart, and thus leading to changes in its structure. In accordance with this idea, Dr. Wilson hinted at the effects of suppressed emotion—the result of the fastidiousness of manner in the present state of society giving rise to the concealment of passion, and quoted the apt expression—“ the grief that does not speak whispers the o'er-fraught heart, and bids it break.”

While the member of modern society smothers his feelings, and thus “ dilates his heart or cracks his arteries,” the child or savage gives vent to his passion in violent gestures, stamping, tossing his arms, and so forth ; by which the blood is impelled to the extremities, and the large vessels are relieved. Increased anxiety is the natural result of the more numerous wants and excited feelings of highly-cultivated life ; and anxiety exerts its peculiar influence on the heart. This influence Dr. Wilson regards as operating in the production of a peculiar state of its fibres ; perhaps resembling that of other muscles liable to be called into sudden action, followed by fatigue. The expressions, “ heart-ache,” and “ serrement de cœur,” were adduced as true to nature, and illustrating the reality of this sensation.

After these preliminary remarks, the author proceeded to discuss more particularly certain cases in which inordinate thickening of the mitral valves was coincident with a remarkable coagulation of the blood in the left auricle and in the lungs. The auriculo-ventricular opening being narrowed by perverted growth, the blood of course was interrupted in its passage towards the ventricle, and thus coagulated behind the obstruction—that is, in the auricle and in the lungs. In two of the cases adduced, the thickening of the mitral valves was inferred before the heart was opened from the black masses of coagulum in the lungs, a similar coincidence having been previously noticed in another case. The preparation of the parts, taken from the subject of the first case, was laid on the table : it exhibited a great and almost complete obstruction to the passage of blood from the left ventricle to the aorta. The auricle had no appearance of cavity—being occupied by a solid coagulum of blood. On removing this the mitral valve was found to be universally thickened, of an almost tendinous consistence, leaving only a short narrow chink, which was still farther contracted by deposits of lymph on the the margins of the valve. On filling the auricle with water the following day, and suspending it by its outstretched sides, the fluid passed only *guttatim* into the ventricle. Reasoning upon this fact, the author observed on the strange state of the circulation in this patient ; during which, however, she sat up, conversed rationally, and discharged all the

animal functions, while the blood was supplied to her system, not in a current of the usual volume, but "by drop and by drop." The patient was placed in the situation of a person with a ligature round the left side of the heart, and lived under its increasing pressure; nor was the fatal termination at length induced apparently by any immediate effect on the heart, but by the blocking up of the lungs, and their being thus rendered unfit for the discharge of their functions. Another circumstance worthy of observation in this case was the state of the animal heat. The body had been removed soon after death to the out-house used for post-mortem examinations, and had remained there for some hours, at a low temperature, but continued so warm that the inquiry into the cause of death was postponed. Without attempting to deduce from this fact all the inferences to which it might give rise, the author contented himself with remarking that it was calculated to illustrate the subject of trance—by proving how inconsiderable an action of the heart, and how minute a current of blood is sufficient for the maintenance of life, especially under circumstances where there is little waste or excitement of the system. The author next proceeded to instance the quiescent state of the sleeping infant. "So motionless is its slumber, that in watching it we tremble, and become impatient for some stir or sound that may assure us of its life; yet is the fancy of the little sleeper busy, and every artery, and every pulse of its frame, engaged in the work of growth and secretion, though his breath would not stir the smallest insect that sported on his lip—though his pulse would not lift the flower-leaf of which he dreamed from his bosom." Yet following this emblem of tranquillity into after life, we see him exposed to every climate—contending with every obstacle—agitated by every passion; and under these varying circumstances, how different is the power and degree of the heart's action, which has not only to beat, but "to beat time" through every moment of a long and troubled life. It is from contemplating the subject in this light that the author is induced to assert that we are apt in general to consider the heart too simply, both in physiology and in disease.

After adverting to the structure of the

heart and lungs as mutually adapted to harmonize in the functions of each other, the author proceeded to enlist among his illustrations of the heart's action under the passions, some of the happiest of Shakspeare's expressions—expressions which, above all others, mark him to have been the poet of nature. Thus we have: "Measureless liar, thou hast made my heart too big for what contains it."—"Else why does my seated heart knock at my ribs against the use of nature?"—"My bosom's lord sits lightly on his throne," and many others.

In conclusion, Dr. Wilson strongly insisted on the necessity of the physician studying man, not as a mere machine, but as a creature of mind and soul as well as matter—not as a solitary being, but as one of "boundless relations and immaterial agencies." He alluded to the "grace and talent" with which this principle of examining into disease by opening the pages not only of "physical science, but of lofty thought and tender emotion," had been recently illustrated within these walls. The paper abounded in classical illustration, and was a true echo—to borrow the author's own words—"of the chord first struck by the master-hand of the president."

ROYAL INSTITUTION,

Friday, March 19,

SIR GIFFIN WILSON, F.R.S. IN THE CHAIR.

Mr. Ritchie's New Photometer.

THE various "Methods proposed for measuring the Intensities of Natural and Artificial Light," were this evening discussed by Mr. Ritchie, and the principles illustrated by numerous experiments.

He commenced by making some observations on the circumstance, that although different kinds and degrees of light, as of the sun, stars, lamps, fires, candles, &c. had been unavoidably noticed for centuries, it is only in comparatively recent times that any attempts have been made to measure with precision their relative intensities. After proving, what every one admits, that Leslie's beautiful instrument is not a

photometer, but rather a photoscope, and shewing that the ordinary plan of estimating the intensities of different lights by the depths of shadow that each will cast, is not so easily judged of by the eye, as contrasting the brightness of continuous illuminated surfaces; he proceeded to exhibit several instruments, both in their original and improved states, which truly deserve their name—*photometers*. The principle on which they are constructed is extremely simple, for they essentially consist only of two discs of white paper, or any other translucent body, or one plane divided into two compartments by an upright of black card, thus, O O, or

 , so that the light from two different sources may be allowed to impinge separately on the same or immediately contingent planes: it is astonishing with what accuracy the eye distinguishes any inequality in the degree of illumination, so that even the difficulty which has by other means been so great, of estimating the relative illuminating powers of different *coloured* flames, may be in great measure obliterated by having some letters in a clear type printed on the paper shields, and ascertaining the facility with which they can be read by different lights, at different distances.

Various modifications of this instrument have been devised for ascertaining the intensity of light under different circumstances; if to measure that of different points of the heavens, two paper discs, which are fixed to the apertures of two tubes with a moveable joint, thus,

 , allowing motion in any angle, and direction to almost any points, however wide apart; and the intensity is measured by adding an extra tube, which will push in or out of either leg to any required length in the brightest, and adjusting the extent until the illumination of the discs at the lower ends next the observer is equal: when the difference in the lengths of the legs will give the difference in the intensity of the light.

The improved photometer recommended by Mr. R. for experimenting on artificial light, consists of the white paper shield divided into its two compartments, as before, by the perpendicular of black card, fitted into a box, with

the ends open, so that the light from the different flames to be examined can fall upon two obliquely fixed mirrors, or inclined planes of paper, and be thence reflected on the paper shield,

thus,  ; to the upper part of which may be attached a blackened chamber, thus,  , through which,

to observe the shield, this appendage intercepts any extraneous light that would otherwise vitiate the result. To use this instrument, the lights to be examined should be placed in the same line, with the photometer between them, thus,  , and if they are

of equal intensities, the distance of each from the instrument will be equal; if they be of unequal intensities, the photometer must be moved more or less towards the weaker light, to render the illumination of the two compartments of the shield equal to each, and then the intensities or different illuminating powers will be expressed by the squares of the respective distances.

This instrument likewise is a very convenient mode of computing the quantity of light intercepted by any transparent substances, by interposing glass, paper, &c. &c. between one of the lights and the photometer, having previously equalized the illumination, and then measuring the distance which the instrument must recede from the one light and approach towards the other, to again equalize the illumination of the two compartments of the shield.

To illustrate the efficacy of the photometer, various experiments were performed with wax candles, argand lamps, oil gas, the combustion of phosphorus in oxygen, and the combustion of lime with jets of oxygen and hydrogen, on the plan proposed by Lieut. Drummond for trigonometrical surveys: the brilliancy and intensity of the latter light is indescribable. Some idea, however, may be formed of it from a circumstance which we observed, although not alluded to by the lecturer, viz. that the oil gas with which the theatre is lighted, notwithstanding it was burning brilliantly, was so completely overpowered that very distinct SHADOWS of the *flames* were cast upon the ceiling; and also from the fact, that it has been seen, as we are informed, at 60 miles

off in a foggy, and at the distance of 100 miles in a clear night.

Specimens of the Phallus Impudicus, &c.

In the library were samples, plans, and models, of Mr. Turrel's proposed method of paving streets with stone set on cast-iron arches; Mr. Arnold's self-registering measure for liquids: various specimens of protophytes from Mr. Burnett's collection, and two examples of that most curious and somewhat rare fungus, the *Phallus impudicus*, found by Mr. B. in Kensington Gardens. This extraordinary vegetable is certainly a *lusus nature* in the most correct acceptation of the phrase, for it has an extremely close resemblance to the penis, the pileus simulating the glans, the stipes the trunk of the penis, the radical intumescence the scrotum, and to complete the mockery, the stipes is traversed throughout its whole extent by a canal, which might be likened to the urethra.

The subject announced for Friday the 28th is, "the Doctrine of Life Contingencies," to be treated by Mr. Brooke.

DR. BURROWS'S LETTER TO SIR HENRY HALFORD.

DR. BURROWS has just addressed a letter to Sir Henry Halford, "touching some points of the evidence and observations of counsel on a commission of lunacy on Mr. Edward Davies." In an article published soon after the commission, we pointed out various particulars in the treatment which Dr. Burrows had experienced, which we thought harsh and unjust. He now speaks for himself, and we think it an act of justice to subjoin some of the more important points; our limits compelling us to restrict ourselves to these. We cannot refrain from directing attention to the curious circumstance mentioned by Dr. Burrows at the conclusion of our extracts.

Having from the first visit taken a very decided view of the nature of Mr. Davies' case, I acted upon it, and gave my testimony in accordance with it. Yet I have been made to feel that integrity of purpose is not proof against malevolence and misrepresentation.

Intending offence to no one, and anxious only to perform my professional duty, it were superfluous to say that I felt surprise at the manifestation of a hostile spirit, which has, from the beginning of this case, never ceased endeavouring to malign me.

The persecution I have endured from this source can only be credited by those who have felt an interest in me, and read the daily papers; or have had an opportunity of seeing the other proofs of it in my hands. During a course of six months, traducement has never ceased. *Ex-parte* police and law reports, false and exaggerated statements, public and anonymous communications, inculcating my motives and conduct, have been circulated through innumerable channels, with a regularity which proves it to be the effect of a system. The object could not be misunderstood; and the nearer the opening of the commission *de lunatico inquirendo* on Mr. Davies, the more frequent and pointed were these attacks. The only cause I can assign for them is, the dread lest my evidence, if unimpeached, should have a preponderating influence on the verdict.

I might have treated this proceeding with contempt, and without apprehension, had I not this proof that it had made an impression I could never have anticipated: about two months after the first newspaper report (August 15th) of Mr. Davies' case, in which although my name was not mentioned, and the falsities it contained were corrected in the same journal on the following day, yet I received a summons to appear before the Metropolitan Commissioners in Lunacy, to answer queries, as it expressed, "with regard to the case of Mr. Davies, noticed in the newspaper." If such were the effect of an *ex-parte* police report on a body composed of gentlemen of rank and education, clothed too with a judicial character, is it to be wondered at if the community were misled and prejudiced?

Indeed, such was the bitterness of the party against me, that during the inquiry I was assailed by numerous anonymous letters, and as soon as the verdict was delivered, my very life was threatened. These did not cease for many weeks afterwards*.

In this excited state of public opinion the commission opened.

* * * *

I shall separately state the five principal charges which Mr. Brougham made when commenting on my evidence, and offer in refutation such observations as each suggests.

I. That I betrayed more the feeling of a partisan than an impartial witness at-

* Out of more than forty of these letters I select, as a specimen, the following, sent the day after the verdict:—"Dr. Burrows is cautioned to take care of himself. His consummate villany will be expiated by BLOOD only."—Dated Dec. 26.

tending to give unbiassed evidence; for I was always desiring to go on my own way, without interruption.

Observations.—On all commissions which I have ever attended, the commissioners have rather encouraged the medical witness to narrate his observations on the alleged lunatic, as being the best and shortest way of obtaining his evidence; and afterwards the court and counsel have examined and cross-examined him. I wished to pursue this course; but Sir Charles Wetherell, perhaps from an imperfect knowledge of the order of the facts I had to state, was, by putting questions relating to those subsequent, interrupting me, to the omission of important intervening facts. I therefore begged permission to proceed in my own course; and in so doing, I merely followed that adopted by all the other medical witnesses.

II. That I was mainly instrumental in sending Mr. Davies to my house at Clapham.

Extract from the Minutes of Evidence :*—

Dr. BURROWS examined by Sir CHARLES WETHERELL.

Q. On the 19th of August Mr. Davies was removed to Clapham Retreat?—A. Yes.

Q. Under the certificate of Mr. Lawrence and Dr. Blundell?—A. Yes.

Q. Did you recommend his removal yourself from the lodgings (in Portland Terrace)?—A. I beg it to be distinctly understood that I did not; nor did I interpose in it in any way. I knew he was going there, (Clapham Retreat), but did not recommend it: it is quite contrary to my practice so to do.

Q. You did not recommend his removal to the Retreat?—A. No; I did not, most distinctly.

Cross-examined by Mr. BROUGHAM.

Q. He (Mr. D.) went there (to his house at Crouch Hill) under the care of two of your men?—A. Yes, he did.

Q. And he afterwards went to Portland Terrace without your having any thing to do with his removal?—A. Yes.

Q. And he came to your house at Clapham without your giving directions for that purpose?—A. Yes.

Q. You were aware he was to come?—A. Yes; I was aware on the preceding even-

ing that he was to be there the following day.

* * * * *

A communication from Mrs. Bywater was made to me the evening of the 18th, that Mr. Lawrence had recommended, and induced her consent to Mr. Davies' going to my asylum, as the best and securest place he could be placed in.

I freely acknowledge that I concurred in Mr. Lawrence's opinion, that, under the peculiar circumstance of a threatened forced removal of our patient, an asylum was the safest place for him. But as Mr. Lawrence had never hinted such a proceeding to me, I went the following morning, the 19th, at half-past eight, to meet him at Mr. D.'s lodgings. I there ascertained that this was his actual advice. The certificate of insanity being legally signed by the two above-named medical gentlemen, and the order by Mrs. Bywater, I gave it to the keeper, and immediately quitted the house, leaving the hackney-chariot in which I came there to convey Mr. Davies to Clapham.

* * * * *

III. That I acknowledged I knew, a day or two before the 19th, that Mr. Davies was going to Clapham Retreat.

Observations.—So far from acknowledging that I knew of Mr. Davies' removal to Clapham *a day or two before*, I have sworn, as already shewn, that I did not know of it till the preceding evening. As a proprietor of the asylum, it was of course requisite to mention such intention to me, and have my permission, before he was carried there.

This allegation requires, therefore, no other notice.

IV. That I put my name to a certificate which was to consign a fellow-citizen to a mad-house, under the restraint of keepers, though for ten days before I had had no opportunity of knowing whether he was sane or unsound.

Dr. BURROWS cross-examined by Mr. BROUGHAM.

Q. Did you not give a written order to two of your men to authorise their taking him (Mr. Davies) on the 4th of August?—A. I sent a note with my men on the morning of the 4th of August, to shew to the master of the Furnival's Inn Coffee House, that they were the persons authorised by me and his family to take him to his own house at Hornsey.

Q. Stating that he was insane?—A. The motive you must assign, of course.

Q. Had you seen him for ten days before?—A. I have just sworn that I saw him on the 31st of July.

* All the extracts from my evidence, or from Mr. Brougham's speech, are taken from the shorthand writer's notes (Mr. Gurney's).

† I affirm, that in no case did I ever recommend a patient to my own asylum in preference to another. Nay, in the last seven years only eight have been sent there upon whom I had been previously attending.—G. M. B.

Q. Not that you saw him?—A. Yes, I have sworn it.

Q. In Philpot Lane?—A. Yes.

* * * *

Mr. Brougham, commenting further on my evidence, asked—"Will Dr. Burrows, or any man living, take upon himself to tell me, that in ten days a man may not be cured?—that in ten days a man may not become as sound as ever man was?"

These questions, doubtless, as they were intended, made a considerable impression on the court. Had it been admissible, however, I would promptly and confidently have replied, that, agreeably to my general experience, and with the knowledge I possessed of the nature of Mr. Davies' case, and the state of mind I found him in on the 25th of July, when I passed more than an hour with him, it was quite impossible, without a miracle, that he could have been cured and sane on the 4th of August.

There was indisputable evidence that his mind had been disturbed for months, and of a gradual and visible change in his ideas, manners, and habits. His malady appeared to be progressive to the time I first saw him, the 7th of July; and as he had never, even after he consulted me, submitted to regular medical treatment, and continued exposed to the full influence of all the exciting causes of his disorder, so rapid a recovery could not occur. In sudden paroxysms of mania, recovery is possible, though not common, in so short a period as ten days; but in Mr. Davies' case I affirm that such a result was impossible.

V. That my evidence was given under the direct bias of interest; for if Mr. Davies was found of sound mind, I should lose all the profits from retaining him in my asylum.

Observations.—I confess I was more surprised at this charge than any other; because Mr. Davies' solicitor, Mr. Hobler, was well acquainted with the repeated efforts I had made, long before the commission issued, to have his client removed from Clapham Retreat; and therefore I conceived that his counsel were equally apprised of that fact; and, being so, that they could never institute a charge against me so easily to be refuted. Nevertheless, the charge was made by Mr. Brougham with all his accustomed impressiveness; and, unfortunately for me, the counsel for the commission found no opportunity of repelling it.

* * * *

Again and again I begged that Mr. Davies should quit my house; and upon these applications much discussion took place between his family and Mr. Jones, the solicitor for, and Mr. Hobler, the solicitor against, the commission. But they could not agree in what other way Mr. Davies should be dis-

posed of. At length, when the day for commencing the inquiry was fixed, Mr. Davies himself declared he would not remove from Clapham Retreat, except force were used, unless he might be permitted to go, free from all control, to his house at Crouch Hill. His determination was approved by Mr. Hobler, and a strong appeal was made to me by both parties to suffer Mr. Davies to remain; and at length I gave a reluctant permission to his staying there till the inquiry was finished *.

* * * *

Viewing, retrospectively, the case of Mr. Davies, and my whole conduct in regard to it, I see no self-accusing act. On the contrary, I maintain that I have not, in any instance, departed from the line which the strictest principles justify.

No blame can attach respecting the medical treatment of him; for, in truth, there was no opportunity of exercising any. During the month which Mr. Lawrence and I attended him, previous to the 4th of August, when he was taken to Crouch Hill, he was never under the least control. His mother would not permit it. Consequently, he adopted or rejected our prescriptions as he pleased. Between the 4th of August and the 26th of December, when the jury pronounced him of sound mind, no prudent physician, under such conflicting circumstances, would have ventured to be responsible for the medical charge of him.

Whether I was right or wrong in my judgment of Mr. Davies' state of mind, is not here the question. Those most competent to judge coincided with me. None, however, who supported the same opinion, need vindication. The event has fully falsified the verdict. It appears that Mr. Davies has never since that verdict was pronounced evinced "a sound mind," nor been "capable of managing himself and his affairs." And, as the climax of this extraordinary case, he now acknowledges that he was, and still is, insane, and justifies those who have affirmed it; and has voluntarily placed himself under the care of two of the physicians who, on the inquiry, gave the strongest testimony of his existing insanity!

May this result teach those inexperienced in the subtleties of intellectual disorders to be less confident in their judgment! May it prove both an example and a warning to future juries on commissions of lunacy! Finally, may it originate some measure to protect British jurisprudence from a similar reproach!

—

* These statements are confirmed by various documents.—E. G.

HOSPITAL REPORTS.

GUY'S HOSPITAL.

Extensive Laceration of the Scalp, with slight Concussion of the Brain.

CHARLES SMITH, æt. 29, driver of one of the Gravesend fish vans, was admitted under Mr. Morgan on the morning of the 18th of February, having received a severe laceration of the integuments covering the back part of the head.

The patient, at the time of his admission, was in a state of stupefaction, but towards the evening he gradually recovered from that condition. When we visited him, which was not until some hours after he was brought to the hospital, he was in a great measure restored from the drowsy state he had been in when admitted, and could answer questions consistently, but as if his attention was occupied by something else, and he remained with the eyelids closed. The right ear was also (independent of the other wounds) torn from the head, with the exception of a very small portion of the upper part; his pulse was 82, small and regular; pupils of their natural size, but fixed; breathing regular, but somewhat quick. During the day he took 15 grains of colocynth, with calomel; and was ordered to be bled to 12 ounces, and cupped on the nape of the neck.

On the following day he complained of a slight pain in the head; pupils somewhat obedient to light and darkness; pulse nearly as yesterday; bowels open. He says he has no knowledge as to how the accident happened; but being subject to fits, supposes he must have been taken in a paroxysm, and falling among the horses, received a kick from one of them; and the nature of the wounds would seem to corroborate his opinion.

20th.—Still complains of pain across the forehead; pulse 76; bowels open from house medicine*; tongue clean; says he has had a tolerable night; pupils more susceptible of the stimulus of light.

22d.—Pain in the forehead continues, and he complains of a pain in the bowels, but has no tenderness on pressure; tongue clean; pulse 74, and regular. As the bowels have not been evacuated since the last dose of physic was administered, the pain which he says he experiences is most probably referable to the medicine.

24th.—He is now up, walking about the ward, and says he has no particular symp-

oms to complain of. The pain in the head has entirely left him; the bowels are kept open with house physic.

March 1.—The patient still continues to do well; the wounds in the scalp, which have been dressed twice since his admission, are nearly healed, and he will very soon be dismissed from the hospital.

Carcinoma of the Penis.

Robert Colebrook, æt. 43, admitted under Mr. Key on the 12th of February, with the above complaint. The patient says it first made its appearance about two years ago, in the shape of a wart, which was situated (according to his description) on the frænum of the glans penis, and gradually spread until the whole structure was implicated in the disease. This state of the parts was attended at times with shooting pains. He applied to a medical practitioner in the country, who at different times excised the excrescences, but in four-and-twenty hours they were as large as ever; and after having attained to a certain size, would frequently (to use his own expression) "rot off," and discharge a thin matter, and sometimes blood. The disease, at the time of his admission, presented an irregular cauliflower appearance, was of considerable magnitude, and discharging a sanious fetid matter. He states that the prepuce, neither previously to the commencement of the disease, nor at any time, was fixed over the glans, but he was able to draw it forwards or backwards ad libitum; since, however, it has attained to a certain size, the prepuce has been fixed behind the corona.

On the 16th, Mr. Key performed an operation for the removal of the disease. This consisted in first passing a piece of tape around the penis and above the excrescence, with a hole in one end, so as to form a loop to suspend the diseased glans; this was held in the operator's left hand, and the integuments and penis cut through together by one stroke of the knife. The bleeding vessels were afterwards secured, and a pledget of lint placed upon the wound; the latter was again removed towards the evening.

On the 22d, suppuration having taken place, an elastic catheter was introduced into the bladder, and directed to be left there until the sore was healed, to prevent a closure of the orifice of the urethra.

March 5th.—Nothing particular has taken place worthy of remark since last report, with the exception of a slight cold and inflammation of the tonsils, and a difficulty of swallowing; which he soon got better of, from the use of aperient medicines and fumigations of vinegar and water. The glands in the left groin had been somewhat enlarged, but since the operation the swelling has subsided.

On the following day to this report, con-

* This is composed of salts and senna, not magnesia with sulphate of magnesia, as formerly stated.

sidering himself well, he left the hospital of his own accord.

ST. THOMAS'S HOSPITAL.

Hæmaturia.

JAMES COUSINS, 25 years of age, by trade a tailor, was admitted into William's ward on the 11th of February, under the care of Dr. Elliotson. He stated at the time of admission that about four weeks ago he was seized with pain and numbness about the region of the umbilicus, which extended down to the pubes, and round to the loins. At this time he passed a considerable quantity of blood with his urine, and continued to do so for about four or five days, when by degrees it became more clear. He now complains of pain and tenderness on pressure over the region of the kidneys, more especially on the right side, which was aggravated at the time he voided blood with his urine. Has pain and tenderness also along the course of the ureters, increased by pressure. There is likewise enlargement of the right testis, which is tender to the touch. He says about thirteen weeks ago he had a severe attack of inflammation of the eyes, and took a large quantity of mercury, when he caught cold, and has not been in a good state of health ever since. The sight of the left organ is diminished, and in a state of incipient amaurosis. Tongue moist, and coated with a yellow fur; sleeps badly; pulse quick. He was ordered to be cupped over the loins to twenty ounces; to take six grains of calomel the following morning, and half an ounce of castor oil at noon, daily.

13th.—Feels considerably relieved by the cupping; bowels freely open; pulse lessened in frequency—is now about 80. Says he was taken last night with vomiting of a greenish bitter matter, whilst in the water-closet; slept more to-night than for the last three weeks; tongue white; not much coated.

15th.—On the 13th, towards the evening, he passed a small quantity of blood with his urine, and a few drops yesterday. Complains of pain in the head, with giddiness and sickness at stomach; tongue clean. There is a slight tenderness over the bladder on pressure, but none along the course of the ureters or over the region of the kidneys; testicle less tender, and decreased in size.

18th.—Mouth sore from the mercury, which he has continued taking every morning since the first dose. Complains of pain in the head, with dimness of sight; bowels open; says he never has the use of them unless after taking the castor oil.

To omit the calomel, and to be cupped on the nape of the neck to twelve ounces.

18th to 24th.—He has a slight pain in the head, but in other respects much improved. On the 20th his urine was high-coloured, depositing a ropy sediment, but we did not perceive any discharge of blood. The dimness of sight at that time had left him, but he still complained of a pain at the back of the head, with heaviness; mouth slightly sore.

29th.—The pain continues in the head, principally referable to the occiput; has passed no blood with his urine; free from pain and tenderness over bladder, kidneys, and ureters; testicle not much affected. Ordered to be cupped over the back of the head to twelve ounces.

March 3d.—The pain at the back of the head much less, but is severe over temples. Ordered to have twenty leeches applied.

5th.—The pain in temples slightly relieved, but his face is much swollen and red, particularly the left side. To have twenty more leeches to the temples. From this time he continued to improve from the pain in his head. His bowels were kept open with castor oil, and on the 9th he was presented cured.

It may be right to observe that he still continued to experience a weight over the head, and had always a dull heavy expression in his eyes. With respect to the symptoms indicating disturbance of the urinary organs, he now made no complaint.

Since this report, the patient has again returned to the hospital, and was admitted into Luke's ward, under the care of Dr. Roots, with a relapse of pain in the loins, from which he has been very considerably relieved by cupping. He now, (March the 27th), complains at times of a violent beating of the heart, on the left side of the chest: nothing indicating morbid structure is heard through stethoscope.

BOOKS RECEIVED FOR REVIEW.

A Treatise on Deformities; exhibiting a concise View of the Nature and Treatment of the principal Distortions and Contractions of the Limbs, Joints, and Spine. Illustrated with Engravings. By Lionel J. Beale, Surgeon.

A Practical Essay on the Disease generally known under the denomination of Delirium Tremens; written principally with a view to elucidate its divisions into distinct Stages, and hence to simplify its method of Cure. By Andrew Blake, M.D.

Fourth Report of the Infirmary for the cure of Diseases of the Eye, Cannon-Street, Birmingham.

LECTURES ON SURGERY,

Delivered at St. Bartholomew's Hospital,

BY WILLIAM LAWRENCE, F.R.S.

— from S

LECTURE XXX.

*Cancer continued—Treatment—preparations of
Iron, Arsenic, Opium—question of Opera-
tion—Fungus Hematodes—Melanosis.*

I MENTIONED to you, gentlemen, in my last lecture, that cancer frequently affects the bones, or rather, that it occasionally does so; and I mentioned to you the instance of a patient who died in this hospital in whom a considerable part of the sternum was converted into a mass of cancerous structure. This [presenting a preparation] is part of the sternum of that patient; and you see that instead of being osseous, it is chiefly composed of a dense carcinomatous structure. This is a specimen of cancerous tubercle in the liver of the same individual, constituting a kind of white mass. The whole liver in this patient was beset with tubercles of the same kind, of various sizes, but not equal in firmness to the original disease.

The symptoms which occur in cancerous affections may sometimes be alleviated by treatment upon ordinary principles; that is, when inflammation is present it may be reduced by the application of leeches, and by the application of soft poultices. The disorder of the digestive organs may be corrected by alterative doses of mercury and mild aperients, together with attention to diet; and the severe local pain and great suffering, which are so troublesome in advanced periods of carcinoma, admit of being alleviated by the local and internal use of opium. The watery solution of opium—the liquor opii sedativus of Mr. Battley, or an ointment made by incorporating finely-powdered opium with lard, in the proportion of one drachm

of opium to seven of lard, may be used locally; while you must administer opium internally, in such doses as to control the pain; in fact, in the last stages of the complaint our medical assistance is pretty much reduced to this mode of alleviating the sufferings. The chlorates of soda or lime may be applied, in the form of a lotion, to remove the fetid smell, either immediately to the sore, or by sprinkling it on the linen which the patient employs. The offensive nature of the discharge is extremely disagreeable to the patient herself and to those about her; therefore this is a point that should not be neglected under such circumstances.

During the period of schirrous swelling, local applications seem to be of little avail. I think it will be found generally that the comfort of the patient is best consulted by keeping the part warm. The breast should be kept covered with flannel, or a portion of hare-skin, so as to keep it at a comfortable temperature. The late Mr. Pearson wrote some observations on the subject of cancer. He said that the plan he had found most efficacious in relieving the sufferings which attended this terrible complaint, was to reduce the diet of the patient to the smallest possible amount. We can easily suppose that a stimulating diet—a diet which consists of a great proportion of animal food and fermented liquors, cannot be very advantageous under the circumstances which frequently attend cancerous disease; that is, in a state of considerable inflammation, and of disorder of the digestive functions. It is necessary generally that this should be attended to, and the patient, at all events, have a mild diet. I do not believe, however, in general that a very low diet will materially contribute to the comfort of the patient. Frequently there is a state of depression of the general powers under which some degree of good nourishment is found of advantage. It has been proposed to cure cancer, or at all events to alleviate greatly the sufferings which accompany its progress, by means of vegetable food, by excluding al-

together animal food and fermented liquors from the diet of the patient. Dr. Lamb has written a work on this subject, in which he states with great confidence that a regular perseverance in a diet consisting of vegetable substances, and distilled water, may be capable, not only of relieving the sufferings which attend cancer—of bringing the ulceration into a better condition, but also, in his opinion, of actually curing the complaint. I think it not unlikely that under some circumstances this plan of diet may alleviate the sufferings of the patient; but I have unfortunately had experience, and that of the most convincing kind, that it is not capable of curing cancer; in fact, not capable of preventing the development of cancer even where it has been employed before the disease has made its appearance. I was well acquainted with a lady, a disciple of Dr. Lamb's, and a warm admirer of his, who had lived on distilled water and vegetable diet for not less than six or eight years. She was originally a healthy person when she began this diet; however, at the end of that time, she became the subject of cancer in the tongue, and in fact died of that disease.

We naturally inquire, finding that the ordinary means of treatment are of so little avail in the management of these complaints, whether there are any remedies—whether there is any plan of treatment which can be considered to have the peculiar power—the specific effect of controlling the progress of cancerous disease? Whether, in short, there are any local or general means that can be called *anti-cancerous*? Sometimes certain substances have been supposed to possess this property. Hemlock, or cicuta, has lost the fame it once possessed in this respect. At one time, and that not long ago, it was supposed to possess great power over cancer. With respect to this and other narcotics, we may observe that any influence they have in the treatment of the complaint results from their power of lessening pain; and when we come to the necessity of employing remedies of this class, I believe we shall find there is none that deserves much confidence except opium. Mr. Carmichael has written a work on cancer, the object of which is to recommend very strongly the internal and local employment of various preparations of iron. He has expressly mentioned that he has used the carbonate of iron, the phosphate of iron, and sometimes the arseniate of iron. He has given the carbonate of iron, in the quantity of from half a drachm to a drachm, in the course of a day. Now we may observe that in various other complaints the carbonate of iron has been administered in larger doses—in doses of a drachm or more two or three times in the course of the day. The phosphate of iron has been given by Mr. Carmichael, in doses of a scruple, two or three times a day.

With respect to the local employment of iron, the carbonate, or phosphate, may be applied in the form of powder to the surface of the carcinomatous ulcer; or they may be applied mixed with water, in the consistence of thin paste; or may be mixed with lard, and applied in the form of ointment. The phosphate of iron, which is a more powerful preparation than the carbonate, sometimes acts as a caustic, and destroys the surface of the part to which it is applied; and thus a considerable change in the ulcer may be produced. The arseniate of iron is somewhat more powerful than either of the others, and destroys the vitality of the parts to a considerable depth; and in this way the arseniate of iron, and arsenical preparations themselves, have sometimes been employed in the treatment of cancerous ulcerations; and frequently, after considerable sloughs have been produced by the application of such substances, the surface has taken on the healing process, and given rise to the appearance of a temporary cure.

I have mentioned already that there is occasionally in cancerous ulcers a partial healing—that the destructive nature of cancer is not so inveterate as to admit of no attempt at repair, under any circumstance. Sometimes, however, even when cancerous ulcers are spreading, there are parts that cicatrize in a healthy way; and it is occasionally found that the occurrence of violent inflammation over the general surface of a cancerous sore seems to lead to the death of the part that had undergone the cancerous change; it becomes separated and detached; and thus the ulcer heals. It is not found that such cures are permanent, but they produce a temporary relief; and I mentioned in my last lecture an instance where extensive cancerous ulceration had almost healed under the anti-phlogistic means which the local inflammation of the surrounding parts required. With respect to the power of iron internally or locally in cancer, I believe we may say it has no effect whatever in curing the schirrous tumor or occult cancer. The internal use of iron in the ulcerative stage may be of advantage, by improving the general health. The system becomes affected in the progress of this affection, and the tonic powers of iron may occasionally improve the digestive powers; it may have that kind of influence on the system in the state of cancerous cachexia which it is capable of producing in other analogous cases. Thus the exhibition of carbonate or phosphate of iron internally, may be occasionally beneficial. We can have no doubt that the local application of the powerful preparations that I have mentioned may be capable of producing a change in the condition of the ulceration in the carcinoma. Yet so limited is the power that we can ascribe to iron in the treatment of cancer that we cannot suppose it possesses

essentially anti-cancerous properties; that it is capable of stopping the progress of the disease—of leading to the restorative process, and thus removing the danger to the life of the individual which the disease always appears to carry with it.

The reputation of arsenic in cancer arises entirely from its power over the ulceration, and its influence when applied externally to those ulcers especially that occur about the face; but we know of no power that arsenic possesses over the original scirrhus tumor, internally or externally applied.

Since, then, we do not possess any power, by means of treatment conducted on general principles, of essentially controlling the progress of cancer; and since we are not acquainted with any substance or mode of treatment that we can suppose to possess a specific power over this peculiar form of disease, we come to the question, how far it may be advisable to proceed by operation? We certainly have the power of removing the disease with the knife; we can cut away the parts that have undergone cancerous change, and thus completely get rid of the disease. The question is, whether such removal be permanent? Whether the disease will recur? Whether we may expect cancer to shew itself again in its original seat, or whether we may expect some of those secondary affections in the various internal organs which I have mentioned to you to become developed subsequently? These are very important questions.

The consideration of the operation brings us again to the question which I have before mentioned—whether cancer be a local or constitutional disease? If we are satisfied that cancer in an early stage is a local disease, we should be inclined to say that the operation of excision—the extirpation of the diseased parts—would at that time be an effectual mode of curing the patient. I think we may venture to say that excision is a safe and effectual mode of proceeding in the indolent stage of scirrhus tumor; that is, when the tumor is loose and moveable, before the skin has become adherent to it, before the tumor becomes fixed to the pectoral muscle, before it has become the seat of any considerable pain, before the vessels have become enlarged, or assumed any thing of a varicose appearance; and particularly before the absorbent glands in the axilla have taken on the disease. At all events, if the operation be not effectual, and cannot be recommended in that condition of the disease, still less can we venture to propose it when the absorbent glands in the axilla have become affected, or the local disease has passed into the ulcerative state.

In operations in the early period that I have mentioned, we have the power of effectually removing the whole of the disease, and taking it away with a considerable por-

tion of the surrounding healthy substance. And in performing the operation for a disease that you have determined to be scirrhus, you must not be economical as to what you remove; you must not think of saving the skin and other parts; on the contrary, you should cut round freely, so as to take away not only the whole of the disease, but all those surrounding parts to which any suspicion whatever can attach. It may be well, if the skin is healthy, to divide it simply, to turn it back so as to remove the tumor, and then to bring it together again, if we are quite satisfied that it is healthy; but if we entertain any suspicion that the skin may be involved in the disease, it is much better to remove it. For the same reason, I have invariably followed the practice myself of taking away the whole of the mammary gland, even where there has been only one small scirrhus tumor in the part; and on examining the gland afterwards, on such occasions, I have usually found such appearances in parts more or less remote from the original tumor as led me to be very well satisfied with having taken away the entire substance.

The next questions then are, is the operation to be considered advisable when the lymphatic glands in the axilla have become affected? Is it advisable when the tumor has ulcerated? I can have no hesitation in stating that the general result of experience is, that the disease returns under such circumstances. You may perform the operation, the parts will unite, the wound will heal, and the patient seem to be restored to health. The operation will thus appear to have been successful; but in a longer or shorter time you find, under such circumstances, either that the disease will return in the situation of the part which has been removed, or that some internal organ will become diseased, and the patient perish in consequence. It appears that the opinions of those who have had most experience in the treatment of this complaint, are generally unfavourable to the performing any operation, even in the early stage of the affection. Without quoting Hippocrates and Celsus, both of whom are adverse to the operation, or any active treatment for cancer, I may mention that Baron Boyer, who is now much advanced in years, and who has had the advantage of great experience in cancer, speaks of numerous relapses of the disease that have occurred even when scirrhus tumors have been removed under the most favourable circumstances. He adds his opinion afterwards that the disease proceeds more rapidly, and that the patient dies sooner than if no operation had been performed.

I performed the operation for a lady who had a scirrhus tumor, about the size of a walnut, seated near the nipple, without any affection of the glands in the axilla. The tumor was quite loose and moveable. I re-

moved the whole of the mamma, and the tumor, when examined, shewed the genuine characters of this disease. I performed the operation in March 1825, and the lady remained perfectly well till the beginning of the present year (1829). In the month of February last she came to consult me, and there was then, at the end of the cicatrix towards the axilla—a part quite removed from the original disease—an ulcerated tumor, and a schirrous gland in the axilla. This lady died in March or April. I only saw her on that occasion, for I considered the case to be totally desperate, and did not propose the operation to her.—I removed the breast of a lady in the month of February 1827. She was a very fine woman—a robust and healthy person. She had discovered the disease about six weeks before I saw her. There was a considerable tumor between the nipple and the axilla, that had been attended with a good deal of pain. The medical gentleman who had seen her in the country had very properly applied leeches, and other means, to remove the local symptoms; but as the affection did not yield to these, the lady came to town, where I saw her. There was then a hard tumor in the situation I have mentioned, with some drawing in, or indentation of the skin: there was no induration of any gland in the axilla. She was about the age of 50, and had ceased menstruating a year or two. She had borne children, and, as I have said, was a very healthy woman. I removed the whole breast, although the tumor occupied but a small part of the gland; and in this instance the characters were those of genuine schirrus. The wound healed extremely well, and she considered herself perfectly cured. Towards the end of the year, however, she began to be ill again—she was indisposed without having any very definite ailment—she got worse and worse. Her medical attendants were at a loss to decide what her complaint might be, but they could not cure her; in fact she died, and no suspicion existed before her death that it was owing to cancer. The cicatrix had remained perfectly sound, and there were no signs of disease in the part originally affected, nor any where else externally. She was examined, and the liver was found an entire mass of schirrus. I did not myself see it, but such was the description given by the gentleman in the country who attended her. Now these are two instances in which the operation was performed under the most favourable circumstances, yet in both these you have seen that the affection was fatal,—in the one the disease returned in the part, and in the other the patient died from similar degeneration internally. Now if this be frequently the case, in instances where the disease is apparently local—that is, confined to the mammary gland—and where

there is no affection of the absorbent glands in the axilla—you may easily suppose that where those glands are affected, there is very little chance of a permanent cure from the operation.

There is another point of view in which the question of operation may be considered, even at a more advanced period than I have mentioned—that is, whether it would be better for a patient to die by the natural progress of cancerous disease—by allowing the part to go to ulceration, with all the sufferings that attend that process; or by removing the disease, to give her an opportunity of dying from the formation of tumors in the viscera, or other internal disorder?

Fungus Hamatodes.

Fungus hamatodes is a disease as intractable and as incurable as cancer, if not more so. Generally, as I have mentioned, it has been confounded with cancer; but the very striking difference between the two in consistence cannot fail to attract the notice even of those who call it cancer. Hence it has gone by the name of *soft cancer*. It is the *medullary sarcoma* of Mr. Abernethy—the *fungus medullaris*, as it is called in Latin. By some writers, from the resemblance of the newly-deposited substance to the texture of the brain, it is named *encephaloid*, or brain-like tumor. *Fungus hamatodes*, the name by which it is now distinguished, was given to it by the late Mr. Hey, of Leeds, who published some remarkable cases of the affection, and noticed one striking fact in its character—that is, its becoming, by ulceration of the skin, a bleeding fungus. Hence he has given it the name of *fungus hamatodes*. The name is in some respects objectionable, for fungus is not necessary to the disease—it may exist and proceed to a fatal termination without ever assuming the fungoid character.

In this disease there is a deposition of a very peculiar substance—it is a newly-formed matter or tumor, like brain, in the cellular texture of any part of the trunk or limbs of the body; or there is a deposition of the same kind of substance in the interior of some particular organ, where it grows, and is developed as a tumor would be in the cellular texture elsewhere. There is this distinction between *fungus hamatodes* and cancer—I think *fungus hamatodes* much more commonly appears as a distinct newly-formed substance in the cellular substance than cancer. Cancer is more commonly seated in some organ—*fungus hamatodes* generally appears as a tumor in the cellular substance of some part of the trunk or limbs. The substance which constitutes the tumor in these cases is particularly characterized by two circumstances—the softness of its consistence, in which it resembles brain—and the admixture of it with a greater or less

quantity of blood, generally in a coagulated state. In colour and consistence there is often a very close resemblance indeed between the newly-deposited substance in fungus hæmatodes, and the medullary or cortical part of the brain: it is soft, and breaks under slight pressure of the finger. It has sometimes been described as a greasy sort of matter. It is greyish, white, brown, or reddish in colour, and very often a diversity of tints is observed in various parts of the same tumor; very commonly coagulated blood is intermixed with this soft brain-like substance. The coagulated blood is found either in streaks or in spots, or in considerable masses disseminated through the substance. Sometimes very large portions of blood are found in it—not uncommonly the whole of the texture is more or less tinted red or brown with blood. There are sometimes cells in the interior of the tumor, containing either fluid blood, or serum.

[The lecturer here presented two preparations, and remarked that they were very good specimens, shewing that kind of intermixture of coagulated blood with the soft substance to which he alluded. One was a tumor taken from the kidney—the other was a specimen of a similar kind, where the tumor had been developed on the surface of a bone.]

The tumor of fungus hæmatodes advances to the surface: when it comes near to the skin, in consequence of the soft nature of the substance which constitutes the tumor, and the frequent admixture of blood in large quantity, it presents a very peculiar feel—a feel of elasticity quite contrasted with the incompressible hardness of cancer. Nay, the softness sometimes goes so far, that a sense of fluctuation is imparted on examination; and this is so deceptive, that not uncommonly the most experienced persons have been deceived by it, and have punctured such tumors under the idea that they contained matter or other fluid. When it approaches the surface, it distends the skin, which becomes tense and shining, and assumes a red colour; after this it is elevated into a nipple-like prominence, which ulcerates, and gives issue to a soft, ragged, grey-looking fungus, from which a thin ichorous fluid discharges in large quantities, or from which copious bleeding takes place. Then it is that the disease properly deserves the name of fungus hæmatodes. The ulceration increases in circumference, and the protrusion of the fungus augments—sometimes the parts slough, and their separation is followed by considerable hæmorrhage. In the progress of the affection and its advance to the surface, and during the ulcerative stage, great pain is experienced, constitutional disturbance arises, the pulse is accelerated, the patient is restless at night, the tongue is white, the stomach and bowels

are disordered; and from the progress of this kind of unhealthy state of the system something like the condition of cancerous cachexia supervenes, from which, together with the effects of the local complaint, the patient ultimately sinks. When we come to examine the body, we frequently find disseminated through the internal organs the same kind of depositions as those which formed the original tumor; tubercles in the liver, lungs, and various other internal parts, as the brain, and even the bones, consisting of a soft substance more or less tinged with blood, exhibiting various hues, differing only from the secondary deposition that occurs in cancer in being softer in their texture. With respect to the secondary depositions, and even with respect to the primary tumor of fungus hæmatodes, I may observe, that when you make a section, and scrape it with the handle or blade of the knife, you squeeze out a sort of cream-like substance; but in other instances the original tumor is firm in consistency. You may have the genuine character of fungus hæmatodes without the brain-like texture, that is, you may have streaks of blood in the same kind of texture that I described, except that the fibrous parts predominate over the softer, and thus the tumor is firmer in consistence. This is a specimen [exhibiting it] of secondary tumor in the brain. The interior of it, you observe, is made up almost entirely of blood.

Fungus hæmatodes very often appears, as I have mentioned, in a primary form, as a tumor in some part of the trunk or limbs, but it also affects primarily a great many organs of the body;—the eye, the skin, the lungs, the liver, the kidney, the ovaria, the breast, the prostate gland, the bladder, the testicle, the mammary gland of the female, the bones, and the muscles. These are parts in which fungus hæmatodes may arise primarily and in a secondary shape too; in fact, when you have tumors formed subsequently to one of these primary affections, they may shew themselves in almost all the organs of the body. This is a very fine specimen [presenting the preparation] of fungus hæmatodes growing out of the substance of the tibia just below the knee-joint, and this too [a second preparation], to which I have before pointed, is a specimen of fungus hæmatodes growing out of the femur just above the knee-joint. The primary disease here [shewing it] was in the testicle of a child, and there are on the table several examples of secondary tumors in the brain.

Now the causes of fungus hæmatodes are at all events as obscure, if not more so than those of cancer. How, indeed, can we explain the origin of the disease, and the circumstances that produce it, when we see the disease developed in the eye of an infant a few weeks or a few months after birth, and

proceeding to destroy the child ; this taking place in an infant that in other respects may be perfectly healthy.

As to the distinction between fungus hæmatodes and other affections, it has been, as I have already mentioned to you, confounded with cancer, though I think the leading circumstances in the two diseases are in many respects strikingly dissimilar. In the first place, there is a great difference in the age of the subjects affected with these two diseases. Fungus hæmatodes occurs frequently in young subjects. In the eye it very commonly occurs under the age of ten years; and in various forms it may take place at all ages prior to that in which we are accustomed to observe the development of cancer. It may come on in an adult at any age, but it is comparatively rare that fungus hæmatodes attacks a person at the same period of life at which cancer most frequently takes place. Then there appears to me to be a strong contrast between the cartilaginous texture and the incompressible hardness which characterize schirrus, and the brain-like softness which denotes fungus hæmatodes. Fungus hæmatodes, as I have already mentioned, comes on much more frequently as a distinct tumor in the cellular texture in various parts of the body;—cancer is rare in that form; it is almost invariably seen to originate in some particular organ. Fungus hæmatodes is more apt to multiply itself externally;—in cancer, although we observe the formation of cancerous tubercles around the original swelling, we usually find that there is no external cancerous affection, except in the original tumor, and the glands that become affected as a direct consequence of this; but it is by no means uncommon to have one or more tumors of the fungoid class in other parts at the same time.

With respect to the *treatment*, I have nothing more satisfactory to offer than the observations that I made respecting cancer—and these were unsatisfactory enough. Treatment is here unavailing, except so far as we are able to administer to particular symptoms. When ulceration takes place, and dreadful suffering comes on, we can only resort to the local and general use of opium. The question of operation here comes to be considered, but there is still less encouragement for its performance in fungus hæmatodes than in cancer. We might suppose that the eye would be a favourable situation for the radical removal of fungus hæmatodes by operation. Now in certain instances, the eye has been removed when the fungoid disease has been completely confined to the interior of the organ, before it has protruded so as to form an external fungus, and when the external coats of the eye have been completely

healthy; yet the disease has returned under such circumstances. This is the tibia—[exhibiting it]—affected with fungus hæmatodes, taken from a gentleman who was under my care. He was about 22 years of age, stout, and nearly six feet high; not a particularly healthy-looking person in the countenance—that is, he was rather of a whitish, pallid, pasty look; but he was otherwise in health. He was affected with pain and stiffness about the knee-joint, at Christmas, three or four years since. On new year's day he was at a party, and having complained of the pain he was told it was rheumatism, and was advised to dance it off. He did dance accordingly, and was able at that time to use the limb freely. He was sensible, however, of some degree of swelling about the knee, but followed his ordinary avocations, and went back to Cambridge, where he was a student. There the local affection soon became much more considerable, and he returned to town. I found a well-defined tumor just below the knee, and a general enlargement in that situation, which led me to suppose that something was wrong there. The disease went on rapidly, and a tumor arose below the joint. It projected externally, and assumed such a form, and fluctuated so distinctly, that, in consultation with another surgeon, we decided that it ought to be opened; and we punctured it to let out the matter—but no matter came. We were then perfectly satisfied of the nature of the affection. A fungus shot out from this opening, but it did not become very considerable. As it was then evident that the disease was fungus hæmatodes, the only question was whether amputation should be performed. Farther advice was had recourse to, and it was decided that the limb should be amputated above the knee. I accordingly performed the operation, and on the sixth day after it he felt himself remarkable well, and was sitting up in bed, enjoying himself with a friend who had visited him. He composed himself to sleep as usual; but during the night the bell rang violently, and when the nurse came down she found him bathed in blood and dead. The ligature had come off the femoral artery, and no union having taken place, he bled to death. On examining the body, there was no internal disease, except a single tubercle of fungus hæmatodes on the edge of the liver; but the glands of the groin were already in a state of incipient fungus—that is, they had the white medullary appearance which is characteristic of the disease. There was a large hole at the head of the tibia, which had been the original seat of the fungoid disease; and on examining the muscles at the back of the leg, a large deposition was found to have taken place, with which all the soft parts were completely penetrated.

The gentleman died in April; the disease, as I mentioned, having commenced at the beginning of the same year.

I was sent for, a good while ago, to a great distance in the country, to see a clergyman who had got an enlarged testicle, which his medical attendant had refused to remove, assigning some reasons why he would not perform the operation which led the gentleman to conclude that he was left to die. He sent for me, and I found an enlarged testicle, the character of which, when I saw him, was by no means very decided; but I have no doubt that it had possessed a well-marked character at an earlier period, for the medical attendant, whom I knew, and who is a cautious man, had considered it to be hydrocele, and punctured it. So satisfied was he, from its feel, that it contained fluid, that, finding no fluid come away on the first puncture, he punctured it again. The tumor, when I saw it, had not that elasticity that would have led me to infer that it was fungus hæmatodes. The circumstances that induced the medical gentleman to refuse to perform the operation, was the enlargement of the spermatic cord. I was of opinion this arose from the weight of the testicle; and I did not consider it a sufficient reason against operating. I stated the reasons to the clergyman for and against the operation, leaving him to form his own determination, which was in favour of its performance. The enlarged cord turned out to be a simple thickening of the part; the testicle itself was of the firm description of fungus hæmatodes—that is, it was of a thick fibrous structure, with a good deal of coagulated blood disseminated through it, much in the manner of the tumor that I have pointed out. The gentleman got well, the wound healed, and he seemed perfectly recovered. He continued well about a year; no relapse or return of the disease took place in the wound itself, but at the end of that time he began to waste in flesh, and lost his appetite. He felt himself ill without having any very definite disease; getting worse and worse, till at last he died. The symptoms, so far as they were of a definite nature, rather pointed to some affection of the chest. He was not examined, but I have no doubt that he died from internal disease—that is, from a development of fungoid disease in some of the internal organs of the body.

You see by these examples, that the result of the operation is by no means favourable in cases of fungus hæmatodes; and there is certainly very little encouragement to perform it where the disease decidedly possesses that character.

Melanosis.

There is another affection on which I have a few words to say, that will detain us but a short time—it is, *melanosis*. This is a

disease very similar to fungus hæmatodes; the original nature of the new deposition seems hardly distinguishable from it; but at an early period the substance assumes a remarkably dark colour, looking as if, in fact, it were thoroughly penetrated with the blackest soot. Hence the name of melanosis has been given to it.

[Mr. Lawrence here presented several preparations, remarking]—Here is a splendid specimen of it, which I am enabled to shew you through the kindness of Mr. Langstaff. This is one of the most beautiful among the specimens in his large collection. If you looked at this, and did not know any thing of it, you would think it was a mass of sooty substance. In fact, the word melanosis, which is derived from the Greek adjective μέλας, black, denotes this striking circumstance in the disease—its black colour. Melanosis is a soft texture, originally very much like that of fungus hæmatodes. It destroys completely the texture of the part in which it is developed, and perhaps makes its way externally, becoming a fungus, from which a thick black matter distils. The disease is also developed in a similar form in various external and internal parts of the body. In that respect it resembles fungus hæmatodes. This is a specimen of melanosis [exhibiting a preparation,] which is, in fact, in the stage of progressive conversion into the black condition. You observe a white and medullary substance in one part, while it is beginning to be black in another.

Now I have chiefly seen melanosis as an affection of the eye. It is developed in the interior of the organ, makes its way out, and forms one of these dark fungoid masses; and if it be not removed in an early stage, it destroys the patient, by affecting the internal organs. This is a very beautiful specimen—[exhibiting it]—of melanosis in the early stage; instead of the clearness of the sclerotic coat, you have a mass of black substance. This was removed from the eye of a young Irishman, about 30 years of age; and, as far as I know, the cure was permanent; at least I saw him between one and two years after the operation, and he was perfectly well. This leads me to observe, that the operation may be undertaken in melanosis with a better chance of success than in fungus hæmatodes. In the early state of melanosis, when you can be confident that it has not extended beyond the original seat in the eye, there seems to be a chance of permanent cure by removing the disease.

In this other preparation which I have pointed out to you before, you see the progress of conversion from the fungoid to the melanoid state, in an eye where the disease had existed longer, and where all traces of the natural structure of the organ is lost—I performed the operation in the hos-

pital, and the patient died about ten or twelve days after it. His liver was enormously enlarged, and filled throughout with melanoid depositions. This is a specimen cut through. Here are large masses of a black substance scattered through the liver, which is itself greatly enlarged: it is the liver of the same man whose eye was extirpated. Here also is a specimen of melanosis in the sternum and ribs, from Mr. Langstaff's museum. This is a very fine specimen of melanosis of the kidneys, where you see the black substance deposited in small spots through the whole of the texture. I think it is the kidney of an ox.

[Mr. Lawrence then handed round a number of engravings, illustrative of the various melanoid appearances which occurred in the eye, the skin, the liver, the lungs, the heart, the pancreas, and external covering of the intestines of an individual on whom Mr. Wilson, of Manchester, operated, for melanosis of the eye; and concluded by remarking, that it must be obvious that in melanosis the only chance of successful treatment must be in the early removal of the disease, when it was yet in its primary stage in the organ in which it was first developed.]

to D.S.

PHYSIOLOGY AS CONNECTED WITH ATMOSPHERICAL INFLUENCE.

By HARDWICKE SHUTE, M.D.

[Continued from page 835, Vol. V.]

Irritability and Sensibility.

WE have already given our reasons for entertaining the opinion that the oxygen expended in respiration is converted, by an animal action, into an animal principle, and that this principle is essential to the continuance of living action, because necessary to that perfection of the animal structure upon which every living action is dependant. We have also, by an inquiry into the nature of the connexion which subsists between the structure and the function of animal matter, been led to the conclusion that oxygen, or rather the animal principle into which the oxygen is converted by the process of respiration, is essential to the continuance of living action, because necessary to the continuance of that property which has been denominated irritability, and which imparts to animal matter its capacity of being excited to action by an appropriate stimulus. Do the several phenomena of life

and of living action admit of a rational explanation consistently with this view of the subject? We are disposed to answer the question in the affirmative, because the property of being excited to action by an appropriate stimulus "is not confined to any particular form of organization—as nerve, muscle, or blood-vessel, but exists in every organ, simple and compound;" and because the phenomena of living action do not appear to be irreconcilable with the proposition, that the irritability of animal matter is in all structures the same. "The irritable fibre, improperly called the muscular fibre, pervades, in our opinion, all organized matter. On it depends organic motion, sensation, and even life; and on it the bodies that surround it continually act, by stimulating it and forcing it to contract. It is of this fibre that I am about to speak, and of the laws that are the consequence of the irritability it is endowed with."

Having thus declared ourselves the advocates of a doctrine which, in the opinion of modern physiologists, has already been weighed in the balance and found deficient, we are imperatively called upon to shew, either that the facts upon which this opinion is founded have, by their misinterpretation, led to an erroneous conclusion, or that the original error consisted, not in the facts, but in the mode of explaining them. Now the opinions of modern physiologists are, it is well known to the reader, much opposed to this view of the subject; and therefore it becomes our duty to inquire how far such opinions are entitled to our assent.

"The more correct opinions of the present day, for which we are in a great measure indebted to the sagacity of Haller, have led us to conclude," says Dr. Bostock, "that all the appropriate actions of the living system may be referred to the two classes of motion and feeling; and that these depend upon two principles inherent in the body—contractility and sensibility; the one seated in the muscular fibre, the other in nervous matter. To the action of one or other of these principles every corporeal change may be ultimately referred; and it is through their immediate operation that all the functions are performed." Having stated that the irritable fibre pervades all organized matter, it is almost unnecessary to add that we are opposed to any doctrine which recognizes

sensibility as a distinct property of the animal fibre. Now "the more correct opinions of the present day are, in our judgment, so nearly allied to error as to involve a contradiction, and be wholly irreconcilable in the phenomena which they profess to explain." If the functions of the animal body are dependent on "a principle seated in nervous matter," there ought surely to be nervous matter for the principle to be seated in; and yet the advocates of this doctrine are, with no little inconsistency, somewhat offended at the bare idea of nervous matter being imagined to exist in all animals. "In order to prove that the latter is the case, it is only necessary to bring forward one unequivocal example of a secretion being produced when there can be no intervention of nervous influence; but of this we have numerous examples in all the various classes of the lower tribes of animals, in which no nervous system has yet been detected. To assert that these animals have a nervous system because they exercise those functions which have been generally supposed to be effected by means of the nerves, when no organs of this kind can be detected, and when the animals are of such magnitude as that their structure can be distinctly examined, is a mode of reasoning which I conceive to be so palpably incorrect as to require no formal refutation." It is obvious, therefore, that the more correct opinions of the present day are, if applied generally, erroneous; and it follows that the fundamental principles upon which the structure of modern physiology has been raised are unsound, because partial in their application, and unsatisfactory, because inadequate to the object proposed. The lower classes of animals are, it may be said, exceptions to, but not subversive of the general law. "Now an exception is part of the thing granted, and must be conformable and not repugnant to the grant, for then the exception is void." An exception, "of which we have numerous instances in all the various classes of the lower tribes of animals in which no nervous system has yet been detected," is so extensive in its application as to constitute a law of itself, and must be so considered until it is shewn that such exception is a part of, and not repugnant to, the original proposition. If sensations be considered as the exclusive property of nervous matter, the fact of sen-

sation occurring without the agency of that matter is not an exception which leaves the original proposition unimpaired, but is subversive of, because wholly irreconcilable with it. But, says the physiologist, the lower classes of animals are unwendowed with sensibility, because unsupplied with a nervous system. Is it surprising that "physiology is still, with a great many persons, and in almost all books, a work of the imagination," when the fundamental principles of the science are made to rest upon so questionable a proposition? a proposition which, if admitted, still offers no explanation of the undeniable facts that a nervous system has been imparted to the superior animals for other purposes besides that of contributing to their sensibility; and that such purposes are, in the inferior animals, accomplished without the aid of nervous matter. There is, says another physiologist, no analogy between the different classes of animals; a proposition which, if admitted, amounts to a tacit acknowledgment that the science of modern physiology is founded on principles so partial in their application as to be wholly irreconcilable with the phenomena which they profess, and ought to explain. We are now, it must be remarked, adverting to a subject of no little importance—a subject which constitutes the basis of every physiological argument, the fundamental principle with which every physiological proposition must be reconciled; and it follows that the whole science of physiology is more or less involved in the truth or error of the conclusions to which the discussion of this subject may lead us. If sensibility is the exclusive property of nervous matter, and there are whole classes of animals in which no nervous matter has been detected, or can rationally be presumed to exist, it is obvious that a physiological system, which recognizes a distinct property of nervous matter as one of its fundamental principles, must, both in its detail and origin be imperfect, because inapplicable to a large portion of those phenomena which it professes and ought to explain. If, on the contrary, sensibility is allied to that property which gives to all living matter its capacity of being excited to action by an appropriate stimulus—if it is, in other words, merely the term by which we express the co-operation of the mind with the irritability of animal matter—the action of the

mind itself being dependant on the same property, it is obvious that the phenomena of sensation do not involve the immediate operation of a distinct property residing in nervous matter, and therefore do not involve the conclusion that the phenomena of living action, such as they occur in all animals—that is to say, both in animals which have and have not a nervous system, are irreconcilable. In order to establish our fundamental proposition, we shall first endeavour to shew that the property which gives to muscular fibre and to nervous matter the capacity of being excited to their appropriate actions, is the same.

We have seen that the animal principle generated in respiration is, when united with the animal structure, a concurrent cause of its irritability; and we are now called upon to shew that the nervous matter derives its capacity of action from the same source. "This function," says Dr. Kellie, "I apprehend to be respiration; between which and the energies of the nervous system a very intimate connexion is maintained through the changes produced on the blood during the pulmonary circulation. This dependence of the brain upon the properties of the blood maintained by respiration, is evinced by a great variety of observations." The actions of the heart and of the brain are equally dependant on a supply of arterial blood; and the blood returns from its circulation through these organs equally deprived of its arterial character. Can there be a rational doubt that the blood is transmitted to these organs for the same purpose, when we have such satisfactory evidence that the blood in its circulation through these organs experiences the same change, and is deprived of the same property? Can there be a rational doubt that the property of which it is thus deprived is that property which it had acquired in the process of respiration, when we find that the blood equally loses in its circulation through the heart and the brain the power of supporting their actions, and equally recovers that power in its circulation through the pulmonary organs? If the blood imparts to different organs the same property in support of their actions, if the same property is expended by those actions, is it rational to suppose that such property contributes to the support of those actions in a dif-

ferent manner, or that the property to which it gives rise is the same in origin but different in character? If the motive and sensitive organs derive from arterial blood the same property, these organs ought of course to be affected in the same manner by the presence of blood which can no longer supply that property. If the actions of these organs are affected in the same manner by the absence of this property, is it rational to suppose that they are affected in a different manner by its presence? "From the suspended or imperfect respiration, those changes," says Dr. Kellie, "by which the blood is fitted for maintaining the activity of the sensorial system are interrupted; this imperfect blood circulating slowly through the brain directly impedes its functions, and so diminishes the excitability of the motive and sensitive organs that they become torpid." If the excitability of the motive and sensitive organs dependant on the brain be thus debilitated by the interruption of the same influence, is it rational, I ask, to suppose that such excitability is different? It is sufficient for our purpose to say that the fact is undeniably a stronger argument in favour of the identity than of the dissimilarity of the properties "seated in the muscular fibre and in nervous matter."

We have seen, in a former part of these observations, that the irritability of the heart is maintained by a due supply of oxygenized blood; that is to say, by a due supply of the animal principle generated in the lungs; and yet our last argument rests upon the fact that the irritability of the motive organs is dependant on the brain. Is, then, the irritability of the motive organs, as severally derived from the respiratory or nervous systems, a different property? Certainly not! If the fact of this property being thus different in origin is no proof of a difference of character, how, it may be asked, can the identity of origin be an argument in favour of the identity of the principles resident in the muscular fibre and nervous matter? We admit, without hesitation, the force of the argument if the proposition upon which it is founded be correct; but the fact of the irritability of the motive organs being derived severally from the respiratory, or nervous systems, is no proof that these systems supply a different animal property. If the property sup-

plied be the same, there is no reason why the irritability which results from that supply should be different. Are, then, the principles supplied by the respiratory and nervous systems the same? Are we to consider the animal principles supplied by the arteries and nerves, that is to say, the arterial and nervous influences, as the same—the same in cause and effect? We are of that opinion; and shall upon a future occasion, state our reasons for entertaining it.

The blood, immediately after its exposure to the influence of the atmosphere in the lungs, returns to the left side of the heart, and is thence distributed, through the ramifications of the aorta, to all parts of the body, for the acknowledged purpose of supporting the animal structure, and for the obvious purpose, in our opinion, of supporting the irritability of the animal fibre through the medium of its structure. Now it was long the opinion of physiologists, that respiration did not impart to the blood the faculty of supporting living action, even for a short and transient period, without the concurrent aid of the nervous influence; but the phenomena of living action, such as they occur in the inferior animals which have no nervous system, and in those whose nervous system has been accidentally imperfect, or purposely injured, may be considered as justifying the inference, that the blood does acquire, in its passage through the lungs, the peculiar property of supporting living action. The expenditure of oxygen in respiration, and its absorption by the blood, coupled with the fact which we have endeavoured to establish, that the union of such oxygen with the carbon of the blood, and its immediate exhalation from the blood-vessels, does not satisfactorily account for the conversion of venous into arterial blood, fully justify, in our opinion, the inference, that this peculiar property of arterial blood is owing to something acquired in its circulation through the lungs. Now the blood transmitted from the left ventricle of the heart to the brain is, it must be remembered, that blood which has been recently exposed to the influence of the atmosphere, which has acquired, in its circulation through the respiratory organs a something, it has been denominated an animal principle, which is characterized by its property of supporting

living action; and it is therefore obvious that the blood transmitted to the brain has the capacity of imparting to it this principle; a principle, it must be remembered, characterized by the property of supporting living action. Now the blood which is transmitted to the brain arterial, returns to the right side of the heart venous, that is to say, deprived of the peculiar principle which it had acquired in the process of respiration, and immediately passes on to the lungs, where that principle is renewed. Can there be a rational doubt that the principle acquired in respiration is expended in its circulation through the brain? If the phenomena connected with the circulation of this principle through the heart and brain are precisely the same, is it irrational to suppose that such principle is expended in the same manner, and for the same purpose? Is not the fact admitted by physiologists? “The irritability of the heart is allowed to be inseparably connected with respiration, and we are of opinion that this connexion extends to all the muscles.”—“Respiration is a constant and uniform source from which the expenditure of nervous energy can be in some respect supplied.”—“The irritability of this, like that of every other muscle, can alone be maintained by duly oxygenized, that is to say, arterial blood.”—“The brain, it would appear, soon feels the want of the florid arterial stream, by which alone its energies can be maintained.”—“It has been ascertained by repeated experiments and observations, that the demand for oxygen in an animal body is proportioned to its expenditure by muscular exertion.”—“From the excessive languor and debility which is produced by intense thought, independent of muscular exertion, I am convinced that the blood undergoes a greater degree of deterioration by the specific action of the brain in a short time, than what it sustains by muscular motion long continued.”—“It was reserved for Bichât to offer a true explanation of this phenomena: he has very justly stated that, in consequence of the suspension of the respiratory function, the coronary vessels, by which the muscular structure of the heart is supplied, are compelled to carry black instead of scarlet blood, a fact which in itself is quite adequate to explain the cause of the heart ceasing to contract.”—“This

imperfect blood circulating slowly through the brain, directly impedes its functions, and so debilitates the excitability of the motive and sensitive organs, that they become torpid." Do we not collect from these several passages, that the excitability of the motive and sensitive organs is equally derived from the lungs, equally dependent on the respiratory changes of the blood, equally expended by the action of muscular fibre and of nervous matter, equally impaired by the interruption, and equally restored by the renewal, of the principle generated in the respiratory organs? Now the fact of the animal properties denominated irritability and sensibility being dependent on the same animal principle, is not in itself any proof of their identity, inasmuch as the principle generated in the respiratory organs may, by the function of the brain, be so changed as to lose its original properties. It is sufficient to say on the present occasion, that the supposition is not very compatible with the foregoing remarks, since it is obviously admitted by physiologists, that the principles supplied by the respiratory organs, and by the brain, equally contribute to the support of animal irritability. The facts above stated may fairly be considered as justifying the conclusion, that the dissimilarity of the animal properties, denominated irritability and sensibility, cannot be inferred by modern physiologists from their difference of origin; and that the property of sensibility is not, as far as the circumstances connected with the primary cause of this property may affect the question, in any way irreconcilable with our original proposition, that the irritability of animal matter is in all structures the same.

ANALYSES & NOTICES OF BOOKS.

" L'Auteur se tue à allonger ce que le lecteur se tue à abrégér."—D'ALEMBERT.

Observations on the Pathology of Venereal Affections. By BENJAMIN TRAVERS, F.R.S. and Senior Surgeon to St. Thomas's Hospital.

MR. TRAVERS having been requested by the Council of the Hunterian Society to contribute the annual discourse at

the close of his presidency, selected for his subject the pathology of venereal affections, and having embodied his opinions, has presented them to the profession in a volume, small indeed in size, but containing many valuable observations, and much important inference.

Venereal affections are considered by Mr. Travers, as by most other writers, under the two general heads of gonorrhœa and syphilis. Gonorrhœa he regards as capable of being produced by simple inflammation caused by mechanical or chemical stimuli, and therefore as not necessarily implying the presence of any specific quality in the matter. A purulent discharge from the urethra or vagina, the result of inflammation, from whatever cause, is capable of communicating the irritation to other mucous surfaces, either of the same or of another individual. The susceptibility of others, however, to its impression varies extremely in different instances, and even, where strong at first, appears frequently to diminish after a time; a first gonorrhœa being generally more virulent than those which follow, and some after repeated attacks at length ceasing to receive the infection when applied under the circumstances in which it had formerly been readily communicated. Another fact worthy of being borne in mind is, that an individual—at all events a female, may be the passive medium of communication, she herself not suffering from the disease, when, for instance, she cohabits at a short interval with a person who is diseased, and afterwards with one who is sound. In cases of this nature, it is not unfrequent for a man to accuse the wrong party: thus infection may be received of one, and not developed till the excitement of subsequent intercourse, which occasionally hurries on the inflammation; nay, the original source of the purulent discharge so produced, may not have been gonorrhœa commonly so called in either of the females with whom he has cohabited. Thus, says Mr. Travers, "I have known a married man, who had an illicit intercourse, finding himself clapped, and well knowing the chastity of his wife, indignant at his mistress's infidelity; upon which the accused party, deeply hurt at the imputation, has demanded to undergo a professional scrutiny, and has thus cleared herself of the charge. So far as examination can be

relied upon, it has established her soundness. Now, the man having intercourse with his wife and his mistress, and with these alone, it follows that he had become inflamed with the co-operation of his mistress upon the leucorrhœal secretion of his wife, whose sickness had been his apology, 'in forô conscientiæ,' for dividing his attentions; and further, that he had not communicated the disease to his mistress."

Gonorrhœa, it will be observed in these remarks, is understood to imply the purulent secretion which may arise from the common causes of inflammation, and so long as the surfaces remain unbroken, it is the opinion of our author, that no poison is generated. Much of the difficulty attending this part of the investigation he holds to have arisen from the idea, that either gonorrhœa or sores are the product of a particular virus, and that a gonorrhœa necessarily communicates a gonorrhœa, and a sore a sore. This, Mr. Travers maintains, is altogether erroneous; his position being, that inflammation is excited by matter from the inflamed follicles of an unbroken surface, as well as by that from an ulcerated surface; and that "the difference of its effects upon the party who receives it, depends exclusively upon absorption or non-absorption, *i. e.* the formation or absence of a sore, a circumstance often accidental."

If the smallest abrasion take place so as to admit of the absorption of matter, a sore follows, the secretion of which in its turn may also be absorbed. Such absorption, however, is not an invariable consequence, at least so far as the production of any specific appearance is concerned. According to this view, it will be perceived, that the existence of a new surface, and the absorption of its secretion, is made the ground of distinction between simple and specific disease; and further, that if an individual has gonorrhœa without any ulceration about the genitals being produced, he is not capable of having any secondary symptoms; but if there be excoriation, and this form an ulcer, the matter from such ulcer is capable of producing secondary symptoms; or perhaps a simpler mode of expressing what we conceive to be Mr. Travers' opinion is this, that the matter of gonorrhœa is capable of giving rise to

secondary symptoms by its absorption, and that the reason why we do not more frequently see this effect to result is, that such matter is generally applied under circumstances not admitting of its absorption, *i. e.* to the unbroken surface of a mucous membrane. "The absence of secondary symptoms in pure gonorrhœa depends, therefore, not upon any difference in the quality of the matter, but upon a law of the animal economy, that the inflammatory secretions of the sound surface are not absorbed into the system."

Gonorrhœal matter is regarded as the source of those venereal symptoms which follow superficial ulcerations, the distinguishing feature of such sores being circularity and flatness, without induration. They are seldom solitary, and are most frequent at the angles of reflection between the layers of the prepuce, and about the loose investments of the glans. They are indolent, and though they clean readily, yet they heal with reluctance. We should have stated, that affections of distant parts frequently take place in simple gonorrhœa, but these, when they occur, are regarded as sympathetic merely, having no character but that of simple inflammation, whereas the secondary symptoms of the gonorrhœal sore are held to be as distinctly morbid as those of syphilis. They consist chiefly in superficial and diffuse inflammation of the velum palati and uvula, with spots of lymph and shallow ulcerations; of cutaneous affections, slighter and less varied than those of syphilis, assuming most frequently the papular and squamous form. The conjunctiva sometimes inflames, and the membrane of the nares even ulcerates; the flat bones become tender, but the periosteum seldom "inflames to deposition," unless the patient be exposed to the additional influences of cold and mercury.

Mr. Travers entertains no doubt of the Egyptian ophthalmia having been the result of the direct application of gonorrhœal matter to the eye, and asks, "would not the matter secreted by any other acutely inflamed surface, if confined in the folds of the conjunctiva, induce similar consequences?"

In the treatment of gonorrhœal sores an alterative, but not a full action of mercury, is commended, and the same medicine in the form of Plummer's pill,

the oxymuriate, or hyd. c. creta, is advised in the secondary state of the disease, together with sarsaparilla.

"The indication of treatment is twofold, alterative, and tonic; if much pain and irritability be present, a sedative should be added. The readiness with which the disease yields to this plan, steadily supported, it is most gratifying to witness."

The second part of the "Observations" before us relates to Syphilis, a term which Mr. Travers uses for the sake of rendering himself intelligible, not from believing that this form of the disease arises from a poison essentially different from that which causes gonorrhœa. But we prefer giving the author's own words on this point.

"The common notion prevails, that proper gonorrhœa, being a simple inflammatory secretion of the mucous membrane, and not acting as a poison upon the system, the lues or syphilis is altogether a distinct disease. Let us examine this opinion. I have said, that whilst on both sides the surfaces remain sound, no constitutional disease is discoverable. But before we decide that the matter secreted in gonorrhœa and in syphilis have no relation to each other, we must shew that the gonorrhœal secretion being absorbed into the circulation, as in the case of superficial sores, is incapable of producing constitutional, or as they are called, secondary symptoms. Now I aver that such a connecting link between these diseases exists, and is palpable to observation. I have already described the symptoms arising from the absorption of the gonorrhœal matter, and it cannot, I think, be denied that the resemblance is such to those of syphilis, as to establish their very intimate relation, if not their identity. If a constitutional disease be traceable through the medium of gonorrhœal sores in a subject hitherto immaculate, the next step in the inquiry is to determine the operation of a constitution already tainted with the poison of gonorrhœa upon sores of this description. Are not the natural secretions of the bowels, the skin, and the kidney, influenced by the deranged state of the constitution? Are not the morbid discharges from simple wounds and ulcers, having their origin in casualties, also subject to vitiation from a similar influence? We know that the unhealth-

ness of the matter of ulcers and suppurating surfaces, of whatever description, is constantly and truly referred to a prevailing morbid state of the system. Thus, if a poisoned habit contracts a sore, though the sore may have been caused by an accidental læsion of the skin, it becomes at once contaminated, and secretes a virus possessing properties not observed to belong to the secretion of a fresh and healthy system: the property, for example, of exciting upon a new surface an inflamed vesicle or pustule, which is followed by an excavated ulcer, instead of a superficial, raised, or level sore, and which runs into phagedenic ulceration, whether on the glans penis or the tonsil; of affecting parts of the system not within the ordinary range of the milder poison, as the iris and the periosteal membrane; of exhibiting cutaneous eruptions peculiar in colour, figure, &c., and differing somewhat in other respects, though that remains for future research to determine, from the class to which they respectively approximate."

From these observations, it appears that Mr. Travers looks upon the gonorrhœal and syphilitic poisons as the same in kind, and differing only in the extent and mode of their manifestation. Gonorrhœa is, in the first instance at least, purely local; but in syphilis the sore is held to be "as much constitutional as local;" and though it sounds rather paradoxical, the opinion of our author is, that the *primary* sore is a *secondary* effect—the production of a constitutional influence of the venereal poison. In this way a sore of *any kind*, on the genitals of a person whose system is impregnated with the poison of gonorrhœa, is capable of giving rise to a secretion which shall communicate syphilis. Again, however, we shall quote the words of our author, as contained in the following conclusions:—

"1. That absorption does not take place from sound surfaces, and therefore the poison of gonorrhœa, if it be one, is not developed in the system. In the very rare cases in which constitutional symptoms follow gonorrhœa in the absence of a visible sore, I refer their existence to absorption from an ulcer in the urethra.

"2. That gonorrhœal matter, though apparently the simple secretion of an inflamed surface, is capable, when ab-

sorbed into the system, as from sores, of acting as a poison in the production of constitutional symptoms.

“ 3. That the venereal poison is essentially one; for analogous, secondary, or constitutional symptoms succeed to analogous primary sores, in systems previously healthy.

“ 4. That the distinction between the gonorrhœal and syphilitic orders of symptoms, primary or secondary, is demonstrative of the difference between the secretions of a system previously healthy and the secretions of a system already charged with a poison.”

A farther illustration of the extent to which our author regards gonorrhœa and syphilis as different grades of the same disease, is afforded by a supposed, —but not supposititious case. A man marries soon after the cessation of a gonorrhœa, and this shortly reappears, and is communicated to his wife. If, from neglect or reluctance to exposure, the female suffer the disease to continue till excoriation or sore follows, then the matter is absorbed, and, being elaborated in her system, becomes syphilis; exposing her to the liability of sore throat and eruptions, and her offspring, if she breed, to the usual secondary symptoms. In the same way, *mutatis mutandis*, a man communicating successively with females who have gonorrhœa only, may develop in his own system the more concentrated form of the venereal poison; if by accident, or otherwise, a breach of surface be effected.

Mr. Travers is a strong advocate for the use of mercury in this form of the disease, though he of course allows that the constitution is not at all times fit for its exhibition. The states which contra-indicate it, are excessive inflammation on the one hand, and excessive weakness on the other. The first is to be met by ordinary means, the second by sarsaparilla; or if a higher tonic be indicated, by cinchona. The decoction and compound tincture of the yellow bark are, according to his experience, preferable to quina. Often these remedies may be given simultaneously with mercury; and this combination is spoken of in terms of great commendation. We observe that Mr. Travers speaks of the oxymuriate as a gentle preparation, or rather as inducing a gentle form of mercurial action; and on this account he classes it with the

hydrar. c. creta, as applicable to cases where great debility is present; and, in fact, these formulæ are given “as a test of the capability of the system to bear it.”

This brings us to the third and last division of the subject; namely, the injurious effects resulting from the combined action of the venereal poison and of mercury on the human frame; subject to yet farther aggravation from scrofula, from exposure to cold, and from intemperance. After a *coup d'œil* at these, Mr. Travers describes at length a peculiar form of disease, which has fallen under his particular observation, as surgeon to St. Thomas's Hospital, and cases of which have at different times been published in our reports from that institution. With this important narrative we shall terminate our extracts.

“ I shall avail myself of this opportunity to notice a peculiar and very formidable distemper, arising from the unlimited intercourse of young and delicate girls of scrofulous temperament, chiefly with foreign sailors, many of them lascars or men of colour, frequenting the brothels in the vicinity of the East and West India and London Docks. The district of St. Catharine's (until recently converted into docks) was the most notorious for the propagation of this pestilence, and a place in that quarter called ‘Swan Alley,’ has given the sore that appellation in St. Thomas's Hospital. The subjects of the disease are almost exclusively females. I remember only one instance of a boy similarly affected, in whom the disease went unchecked to a fatal termination. The girls are slender, with very thin fair skins, and often light hair, and generally from 15 to 25 years of age. They have been a few months before decoyed by the Jews who keep these houses, and are systematically on the look-out in the great neighbouring thoroughfares. The girls, newly arrived in London, while in search of lodgings until they procure places, become victims to these miscreants.

“ They receive the visits of as many men as there are hours in the day, and are supported on scanty food and abundance of gin. Their visitors do not always restrict themselves to natural connexion. When they become constitutionally ill, their keepers send them to the hospitals. The Magdalen ward of St. Thomas's is seldom without one or

more of them. They have been only two or three days in the house, when the character of the sore displays itself; for by reason of the previous illness they are rarely detained in their occupation long enough for the ulcer to have assumed its genuine features. It is a circumscribed irregular ulcer with an inflamed blunt edge, usually situated at the lower angle of one labium, or in the cleft of the nates. When the sore inflames, its edge acquires a dark crimson colour to some distance around; the surface is covered with a deep, tenacious, ash-coloured slough, and it extends so rapidly, as to be increased visibly from day to day. It is generally attended with excessive unremitting pain, a very rapid and contracted pulse, great paleness of the surface, total failure of the appetite, and great depression of strength and spirits. It is, in fact, acute gangrenous inflammation. Where they recover, no secondary symptom of lues appears; nor is the disease in any degree contagious. The treatment now adopted seldom fails to arrest it, unless admitted in a very advanced stage, as after the sloughing process has been some time established, when the devastation is truly terrific. In addition to the slough of the pudendum, I have seen the entire lower opening of the pelvis deprived of its soft parts. The girl dies typhoid with a dry black tongue, and is first delirious, then comatose.

"When the pain is severe, and the disc of inflammation strongly marked, blood-letting is beneficial to both. I usually apply lint soddened in a saturated solution of the extr. opii, over this a poultice of linseed meal, and cover the whole with a fomentation flannel. This seldom fails to relieve, if not to remove the pain. The exposure of the sores and the change of dressings much augment it; the continued application of warmth and moisture as much abate it. After clearing the bowels with castor oil, I give a draught of camphor julep with a drachm of ether, and ten minims of the tinct. opii every four hours; and half a grain of opium additionally, if the pain is very urgent. If the slough is fast, and the ulcer extends, the surface is washed freely with the strong nitric acid, and it is remarkable that very shortly afterwards the girl expresses great relief. The London treacle poultice I likewise find an excellent application, covered by the fomentation flannel. The object to be looked to for directing

the application, is the colour of the surrounding skin; when this pales, the dilute nitric acid lotion, ten drops to an ounce of water, is the best application. Fresh eggs and milk, and as the stomach acquires tone, a mutton chop, and from ten to twelve ounces of port wine daily, are an appropriate support. The occasional repetition of the oil or the common enema should not be neglected under the habitual employment of opium.

"The strong acid must be repeated each third or fourth day, till the whole surface granulates. When the girl sleeps and takes nourishment, notwithstanding an immoderately quick pulse, she does well; and the sore, when once clean, heals rapidly under the dilute acid lotion and simple cerate. The bark is useful at this period, but very secondary to the opium, wine, and nutriment. The former should be gradually reduced. A lotion of the chloride of lime and caustic soda, three drachms of the first and one drachm of the last to half a pint of water, acts with magical celerity in clearing the sloughs in many cases; but I have not found it so applicable or efficacious during the stage of acute inflammation, as when it is subdued. I once saw mercury rubbed in to rapid salivation, with manifest acceleration of the destroying process, and the vital powers were further greatly sunk by it. I have seen the inflammation begin after the taking of half a dozen blue pills, one every night and morning, which had been prescribed upon the girl's admission for a sore, which was then small and indolent, in ignorance of its character and tendency.

"I have known a gonorrhœa return, which had been suspended during the inflammation, accompanied by an obstinate form of warty excrescences, but never discovered any symptoms of the venereal poison. The girls cohabit for weeks, or even months, upon a gonorrhœal discharge or excoriation; and I believe that the continued excitement to the affected parts—in constitutions half formed, yet exhausted by incessant stimulus, and the total disregard of cleanliness—induce, as soon as active ulceration commences, the gangrenous phagedæna. This character of the inflammation in its onset is sufficient to prevent the secretion of the venereal poison. Its effect is like that of a caustic to a recent chancre.

"I cannot admit that this sore results

from the irritation of the matter of gonorrhœa; and as little, that it is an affection altogether local and requiring only local treatment. It is sufficient answer to the first that gonorrhœa is not always present, and that it sometimes appears distinct from the pudendum, as on the ilia and abdomen, as well as consecutively to sympathetic bubo. One of the most formidable cases I ever witnessed was in this situation. With reference to the second point, it is by no means a warrantable conclusion from the occasional efficacy of local remedies in promoting healing, and repeated observation has satisfied my mind that the disease essentially depends on the existing state of the habit. I am quite ready to admit that material difference prevails in the symptom of pain, and that occasionally a state of torpor, amounting to apathy, prevails. But this is equally a morbid state, and these are the exception cases. That the abuse of spirituous liquor, that worst abuse which renders its continual excitement a substitute for nourishment, has much to do in determining this gangrene, is proved by the fact that a similar description of ulcer occasionally attacks young men; for example, sailors who have kept up a continued system of drunken debauchery after their return from a voyage, and others, without any affection of the genitals; sometimes appearing upon the limbs and sometimes upon the trunk of the body. I have seen precisely such an ulcer as that above described upon the abdomen of a young man, in circumference equal to that of a small plate, and the deep dense slough by which it was filled irremovable by applications of any kind."

The volume concludes with some remarks on the history of the venereal disease, in the course of which Mr. Travers expresses his belief that it did not come originally from America; he regards the disease as having undergone great change in its symptoms since it was first observed by the earlier writers; but that the poison is still the same, "one and indivisible." The essay, though short, is evidently the production of one who has thought much upon the subject. It evinces that partiality for abstruse research which characterizes the writings of the accomplished author; and thus requires considerable attention in the perusal. This we have bestowed upon it, and

trust that we have given, though a condensed, yet a tolerably correct and perspicuous view of the doctrines it contains.

Illustrations of some of the principal Diseases of the Ovaria, their Symptoms and Treatment: to which are prefixed, Observations on the Structure and Functions of these parts in the Human Being and in Animals.
By EDWARD J. SEYMOUR, M.D.
With 14 Lithographic Engravings.

As we made the public acquainted with Dr. Seymour's valuable observations on the physiology and pathology of the ovaria, when they were delivered at the College of Physicians last year, we have no occasion to direct the attention of our readers to the subject on the present occasion. We think it right, however, to inform them, that the descriptions are now illustrated by a set of very finely-executed lithographic delineations, which it is not too much to say have never been excelled by any plates of the kind which have appeared. These engravings add very much to the interest of the work, and are published at so cheap a rate, as to shew that the design of the author has been to render them easily accessible—profitable to himself, at their present price, they cannot be.

ON THE EXTIRPATION OF STEATOMATA FROM THE SCALP, &c.

By T. W. CHEVALIER, Esq.

EVERY surgeon is aware of the inconvenience that frequently arises in the attempt to remove those small encysted steatomata which not uncommonly occur in the human scalp, and which appear to consist of one or more sebaceous glands enormously enlarged, and distended with a suety substance, little different from their natural secretion. The capsule of these tumors is often so exceedingly delicate and pellucid, that we can hardly ascertain its complete removal, unless by good fortune, or by skill on the part of the operator, it is extirpated entire; whereas, if the smallest portion of it should remain in the wound, the disease is liable to return.

In the uncertainty occasioned by the accidental puncture of one these cysts,

I have seen two methods employed; namely, the excision of a much larger quantity than necessary of the parietes of the cell in which the tumor was lodged, whereby the patient suffers more than is requisite in so trivial an operation; or else the introduction of caustic into the wound, for the purpose of destroying any portion of the capsule left behind, and of preventing union by the first intention; and in this case, the use of the knife might as well have been dispensed with, for it is always sufficient for the cure of these tumors, and sometimes the most eligible treatment, to puncture them with a lancet, and, having squeezed out their contents, to introduce into the cavity a portion of kali purum for a few seconds; after a day or two, the capsule comes away entire, and the wound readily and permanently heals.

A slight alteration in the form of the common scalpel, however, has enabled me to ensure the removal of steatomatous and other tumors of a similar kind, without the rupture or puncture of their capsules; and in general, the small inverted pyramid, or graduated compress of lint, with which I have dressed the wound in the first instance, has come away after a few days, leaving the part healed.

Fig. 2.

Fig. 1.

It is evident that the point of the scalpel, Fig. 1, pressing upon the ex-

ceeding narrow surface which supports it, will indent the elastic and delicate capsule under an equal degree of pressure, to a deeper extent than the wider extremity of the blade, Fig. 2. The former will, therefore, communicate to the hand, *cæteris paribus*, a less sensible resistance than the latter, and be so much the more likely to lay open the capsule, which it is also liable to puncture. Experience has shewn me that a round point, or rather a round edge, such as is represented in Fig. 2, will cut with equal certainty, truth, and precision, while the extent of its effect in every stroke of the knife may be far more accurately calculated, and more securely depended on, than that of the scalpel in common use, which indeed must often operate as a *single-toothed saw*, if I may use such an expression, rather than as a knife; and in all cases in which small tumors, either of delicate structure, or deeply imbedded in the neighbourhood of important nerves or bloodvessels, are to be removed, I have long been accustomed to prefer the former.

As I have had occasion to advert to the method of curing steatomatous tumors by the application of caustic, so as to effect the sloughing their cysts, I may be permitted to add, that I have employed, with success, a practice not very dissimilar for the cure of small and recent *ranulae*; but in these I have used the *argentum nitratum* after puncturing the tumor, introducing it only for a second or two, so as to obtain the obliteration of the cavity, not by its destruction, as in the former case, but by adhesive inflammation, acting precisely upon the same principle as in the cure of hydrocele by injection.

I have known caustics employed in the same manner for the cure of *ganglia*, but without any necessity; for if these tumors be large enough to produce inconvenience, they may in almost all cases be easily burst, by firm pressure made with a strong narrow splint upon the integuments immediately covering them; and by this simple means I have obtained the *instantaneous cure* of many *ganglia*, without any symptom of pain or inconvenience, and without any injury whatever to the skin.

REMOVAL OF THE SUPERIOR
MAXILLARY BONE.

—
To the Editor of the London Medical Gazette.

SIR,

I REQUEST you will insert the accompanying statement in one of the earliest numbers of the Medical Gazette, and oblige,

Your very obedient servant,

JOHN LIZARS.

Edinburgh, 34, York-Place,
12th March, 1830.

In Number 98 of the London Medical Gazette, you inserted the report of an operation which I performed in the Royal Infirmary, for the removal of a superior maxillary bone affected with a medullo-sarcomatous tumor in its antrum; but your reporter erroneously stated that the patient "had laboured under general dropsy three weeks previous to admission." I beg leave to inform you, in correction, that the time was three years; and that I consulted the physician, Dr. Saunders, under whose care she had been for the general dropsy, with regard to the state of her health, immediately prior to the operation. Indeed I am somewhat surprised that your reporter has not availed himself before this time, of the ready means for rectifying so palpable an error.

I performed the same operation on the 10th of January last, on a woman of 55 years of age, and was enabled to remove the whole disease. The patient was placed under my care by Dr. Simmons, of Dumfries, and she has this day left Edinburgh perfectly cured. As the steps of the operation were nearly the same as those detailed in No. 98, it seems to me unnecessary to recapitulate them. Little or no irritation followed the operation, and the incisions of the face united both kindly and thoroughly. This operation was proposed by me in 1826, in Part 9 of my Anatomical Work.

THE LATE DR. WOLLASTON.

—
To the Editor of the London Medical Gazette.

SIR,

IN the memoir of Dr. Wollaston, that lately appeared in your respectable publication, it is stated, that he was *senior wrangler* of his year*. This is a mistake—it was his elder brother, the late Archdeacon Wollaston, of Southweald, in Essex, who had that honour. The Archdeacon was of Sydney, and was senior wrangler and first Smith's prizeman in the year 1783. He was afterwards (as the Cambridge Calendar informs us) fellow and tutor of Trinity Hall, and Jacksonian professor of natural and experimental philosophy.

Dr. Wollaston was of Caius College, of which he died the senior fellow; and as he went out in physic (that is, took his bachelor's degree in physic, without the intermedium of arts), he was precluded from any competition for University honours, which is limited to such as stand for the degree of bachelor of arts. This was a serious disadvantage in the education of a physician at Cambridge, which is of late, I believe, in some degree corrected.

Dr. Wollaston had a Tancred scholarship in physic when at the University; and as this requires that the holder should take the degree of bachelor of physic as soon as he may be of sufficient standing for it, Dr. Wollaston was by this means deprived of the high position in the mathematical tripos which, in all probability, he would have otherwise obtained.

No man ever existed who possessed a greater variety of accurate knowledge than Dr. Wollaston, or a more happy talent of applying it to the objects of his researches; and when to these we add the singular and innate keenness of his perceptive powers, and his powerful and comprehensive faculty of observation, to which every sense was eminently subservient, it is not surprising that his numerous and valuable philosophical labours should be stamped with a character which is so peculiarly their own.

I remain, sir,

Your obedient servant,

X. Y. Z.

* On the authority of the Annual Obituary.—E. G.

ON THE

EFFICACY OF SUPPORT, AND THE
LOCAL APPLICATION OF MER-
CURY,*In Chronic Inflammation of Glandular Structures, but of the Testicle in particular.**To the Editor of the London Medical Gazette.*

SIR,

I BEG leave to direct, through the medium of your columns (if you have one or two to spare, and think them not unworthily occupied by these observations), the attention of the medical world to the reduction of chronic glandular enlargements, more particularly those of the testicle, by support and the local application of mercury. It is true this subject is not new; we have all seen numerous instances where the mercurial friction, &c. in these cases, have been of essential service; we have seen it disperse them; yet I think every one will admit that he has witnessed it also with a very unsatisfactory result.

We are indebted to Mr. Scott for the improvement which he has made upon the treatment of these cases. Nor am I unwilling, as an individual member of the profession, to acknowledge how much I am indebted to that gentleman for the success which I have found attendant upon the employment of mercury and support, agreeable to the method recommended by him. Indeed I believe I may say that I have not since met with a case of simple chronic inflammation, unattended with malignant disease, which has failed to give way, in a most satisfactory manner, where its application was admissible. In illustration of this, I have connected with these observations two cases of chronic inflammation of the testicle.

CASE 1.—In August 1829, I was applied to by Capt. —, a strong athletic man, but of a constitution rather tending to scrofula, in consequence of a very considerable enlargement of the left testicle. He had just then arrived from St. Petersburg, after a very cold, wet, and tedious passage. The absolute necessity of his attending to the duties of his ship, prevented the opportunity of using such active measures as would have been advisable under more favourable circumstances. In a few days he

left England on another voyage, and returned again about the commencement of December, when he applied to me. He had one of the cervical glands enlarged to the size of a walnut, and softened; his skin looked of an unhealthy hue; he was irritable and nervous, and perspired copiously with the least exertion, and had lost flesh considerably. He had a constant, short, tickling cough; the tongue was furred, and the bowels inactive. He said he did not feel ill, yet it was clear that he was suffering under general functional derangement.

The testicle had increased to an enormous size—as large, I may say, as a well clenched fist; it was very hard and ponderous; he suffered no pain from it, nor indeed had he from the commencement complained of any, save the inconvenience produced by its weight, and which caused an uneasy dragging sensation along the cord, and numbness down the thigh.

It will be seen that he had been four months in this state, without the least prospect of amendment; his health was rapidly giving way, under the irritation and anxiety of his condition, when, on the 8th of December, I subjected him to the treatment recommended by Mr. Scott: that is, having first well washed the part with strong camphorated spirit, on a piece of lint, adapted to the size of the testicle, is spread very thick a cerate composed of strong mercurial ointment and soap cerate, of each an ounce, well rubbed down with a drachm of finely levigated camphor. This being adjusted, strips of adhesive plaister, for the triple purpose of securing it, preventing exhalation, and giving support to the testicle, are then applied; bracing it well up by attaching them first to the perinæum and then to the abdomen. These strips being liberally supplied, the whole is encased in leather, covered with equal parts of soap cerate and resin plaister, cut so as nicely to fit the part and combine the whole together. As there is a disposition in the plaisters to be drawn up from their attachment to the perinæum by the action of the abdominal muscles, this will be prevented by passing a tape through that part of the leather which is attached to the perinæum, and making it fast to the back part of the circular band of the suspending bandage.

On the 13th, the 17th, the 26th, and

the 31st, the plaisters were renewed. By the 17th, a very evident diminution had taken place in the enlarged testicle, attended with as great an improvement in the general health as I ever witnessed within so short a time. On the 9th of June (being just one month from the time of his requesting my attendance), with the testicle very nearly reduced to its natural size, and in the enjoyment of excellent health, he left London to enjoy the shooting season with his country friends.

I shall merely state that this patient took no mercury, as it is not my intention to comment upon the ability of being able to dispense with the administration of mercury in those patients who are generally the subjects of chronic disease. He took a drachm of the extract of sarsaparilla night and morning, and every third night five grains of camboge, of scammony, and of the ext. of colocynth. The gland in the neck, above-mentioned, had entirely disappeared.

CASE II.—On the 13th December, 1829, I was desired to attend Mr. —, resident in the vicinity of the Commercial Road. I found him rolling in bed, from the agonizing pain of a swollen testicle. This attack was brought on by more than customary exercise. He had been the subject of an enlarged testicle now twelve months, and this was about the thirteenth or fourteenth time that, upon the least exciting cause, he had been necessitated to undergo the painful and never-ending ordeal of leeches and lotions, &c. I had never seen him before, and upon examination I found the left testicle enlarged, yet not so much so as in the former case. It was drawn up to the groin, and extremely sensitive to the touch. Two or three days had now elapsed since the commencement of the attack, during which time he had not slept, and had, as may be supposed, an attendant fever.

As active inflammation had again taken place in the testicle, I applied leeches, with frequent warm emollient poultices. He had a brisk purgative and an anodyne at bed-time. Under these means, on the 17th he found himself as well as he had always been after his previous attacks. I commenced now with the mercurial dressings, and with the pills and sarsaparilla, as in the former case. On the 22d and 28th of

December, and on the 2d, 11th, 19th, and 28th of January, the dressings were renewed. On the 5th of February I removed them for the last time. The testicle was now reduced to the size of the healthy one; he declared himself to be entirely free from all that miserable dragging sensation along the cord, and numbness of the thigh, which had so annoyed him during the last twelve months; nor did his general health fail to indicate the relief it had obtained from the cessation of local irritation.

I could relate many more of these cases, but I trust it is unnecessary. The success which has attended the above treatment has given origin to these observations, under the feeling that those who have or may have such cases, and have not yet tried this method of the local application of mercury with suspension, might, from these remarks, be induced to do so, and thus tend to the amelioration of human suffering.

I am, sir,

Yours, &c.

JAMES YORK, M. R. C. S.

High-Street, Whitechapel,

MEDICAL GAZETTE.

Saturday, April 10, 1830.

"*Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.*"—CICERO.

UNPOPULARITY OF DISSECTION IN IRELAND.

It would be very desirable that on a subject of so much importance as that of providing for the anatomical wants of our profession, there should be as few misconceptions afloat as possible. Prejudices, we know, do abundantly exist in certain high quarters, as well as in the lowest grades of society; but we are sorry to add that some very mistaken notions are also to be found within our own professional pale. They are not, indeed, entertained by more than a very few individuals; but it were bet-

ter there were no shades of distinction, however slight—no varieties of opinion on the subject: we should have no schisms amongst us. For before we can reasonably expect to make converts to our views—these must be clear and well-defined—we must be agreed amongst ourselves, and well assured of their propriety, otherwise we only exchange error for uncertainty. What we would now more immediately advert to are certain statements of Mr. Guthrie, made in his first lecture before the college; and the concurrence in his opinions, expressed in the last number by our esteemed contemporary, of the *Medico-Chirurgical Review*. They will have it that none of the existing prejudices against anatomy arise from the practice of dissecting murderers; and the learned lecturer adduces, in confirmation of this opinion, a certain supposed or ideal state of things in the sister kingdom. We had better repeat his own words:—“In no country in the world is dissection more freely and fairly carried on than it is at this moment in the city of Dublin. Whilst it is endeavoured to be instilled into the minds of the profession here that it is because murderers are dissected that subjects are not to be procured, we find that the profession in Dublin take an opposite course; we find that they are fully convinced and satisfied that it has no influence upon the public mind; we find that there is no place where bodies are obtained so readily (they are obtained almost for nothing;) there is no fear of dissection; they are capable of doing as they please; yet we find them actually selecting the bodies of murderers; not only seeking them for dissection, but publishing, in the face of the whole country, the experiments performed on them. But if any ground of suspicion, that the prejudice depended upon the anatomizing of murderers were entertained, this would be most indiscreet, and might put a stop

to the freedom of dissection which at the present moment prevails in Dublin. We find, on the contrary, that they not only open these subjects, but perform experiments upon them, and publish the result in the newspapers. We see that they are not afraid of these descriptions going forth, and we may therefore reasonably and fairly suppose that there is an error upon this subject*.”

All this certainly seems to be a very plausible argument—nay, it is quoted by our contemporary as “unanswerable”: it happens, however, to be a mistake, and the answer to it is simple and conclusive. Mr. Guthrie is not aware, or has been misinformed, of the actual state of practical anatomy in Ireland—how it stands in public estimation in that country. There can hardly be a more mistaken notion than to suppose the Irish apathetic, as they are here described, or that they look with indifference on the practice of dissection: very far from it: it is with feelings of strong repugnance that it is contemplated by the mass of the people; and all its frequency, and alleged publicity, have not succeeded in rendering it less abhorred in their sight. This we will prove to be the fact in the first instance, and then we shall trace it to its proper causes. Be it observed that we now speak of the people—the populace—the mass of the Irish community. The circumstance of some two or three hundred individuals of the better informed and higher classes voluntarily tendering their bodies for dissection, serves only to confirm our position; the express object of those friends of anatomy being the removal of existing prejudices from the minds of their fellow-countrymen.

It is not necessary to go far back for instances of the popular hatred with which dissectors, and all who are known to have any connexion with them, are

* See *Med. Gaz.* No. 119, p. 759-60.

viewed in the Irish metropolis. We have heard of houses being pulled down by a furious mob, upon bare suspicion, when a phrenzy was excited against their anatomical inmates by some untoward accident. But recent examples are most available. About the time of the universal panic inspired by the discovery of the Edinburgh atrocities, it is not to be supposed that Ireland slumbered in a state of philosophic indifference, or disregarded the horrible narratives then currently circulated; on the contrary, she sympathized fully with the general feeling, and, as is usual on such occasions, rumours were readily taken for realities—trifles light as air, for confirmation strong. Mr. Kirby's school, in Peter-Street, was beleaguered for many days, and laid under serious embargo, in consequence of a frolic played off on a schoolboy by some of the students. The urchin had made himself troublesome about the door, and was carried into the dissecting-room by way of punishment; but his companions who remained outside soon raised an alarm, and the house was speedily in danger of being pulled about the ears of the unlucky dissectors,—"the sack'em ups," as they began about that time to be denominated. The affair was at length arranged—but not without much difficulty—by the interference of the magistrates of police. Here the disturbance was mainly owing to the ideas vulgarly entertained about dissecting-rooms, and the dark deeds supposed to be done therein. In Dublin, just as in other cities of his Majesty's dominions, anatomists must proceed with fear and trembling; they are obliged to work by stealth—and stealth cannot escape suspicion, nor suspicion persecution; and perhaps there is as much of that persecuting spirit in the Dublin mob as in any other mob in the empire. Against resurrection-men, and that class of gentry, it

rages with peculiar violence: neither will it spare the softer sex, when suspected of being engaged in the service of "the surgeons." Not long since, two poor creatures who were observed carrying a coffin through an obscure street in the outlets of the city, were stopped short in their pious offices; the coffin, which contained the dead child of one of them, was wrested from their hands, and the miserable mourners narrowly escaped strangulation. Still more recently, we have heard of another outrage of a similar nature: an elderly woman who carried a box, the contents of which, it appears, she knew nothing about, attracted the attention of some idle boys. It happened to contain a small skeleton—a withered affair of some thirty years standing—which her master wished to have conveyed to his new lodgings. But the old lady seems not to have been one of the best of messengers; she diverged from her onward track, and speedily fell into harm's way. The box was soon scented—somebody got a peep into it, and raised an immediate hue and cry. In short, she was concluded to be the mother of a gang of resurrection-men—a second Mrs. Hare: she was dragged through the streets, and almost pulled to pieces—pelted with mud, and treated with every sort of cruelty, until she at length found shelter and protection in a police-office. Now be it borne in mind, that this was a portion and fair sample of the very same populace that extended their commiseration and tender mercies to the perpetrators of one of the most cruel and audacious murders that has disgraced any European city in modern times. The sawyer Hanlon was beaten to death with clubs in the open day, in a crowded street, by a band of combiners, in presence of at least a hundred witnesses. Yet evidence could not be procured by the crown, except by the temptation of a great reward.

Four of the villains were hanged and anatomized, "according to law;" and though, when the execution was over, it was generally admitted that the wretches had richly deserved their fate, yet the executioners of the gallows and the dissecting-room were involved in one common cry of obloquy—both were loaded with execrations. Every sort of hostile demonstration was exhibited by the daring mob assembled in York-Street during the Galvanic experiments and dissections. The College would undoubtedly have been stormed, were it not for the protection of a strong body of armed police;—as it was, many instances of insult and assault on professional gentlemen might be enumerated.

In truth, the pursuit of practical anatomy in Ireland is very far from being uniform and uninterrupted; comparatively, perhaps, with other cities, much in the dissecting department is done in Dublin; but it is by no means smoothly done, "fairly and freely," as Mr. Guthrie describes it; on the contrary, it is much more through evil report than good report. Scarcely a day passes in which the Irish newspapers do not contain some details of skirmishing and warfare between the retainers of the schools and the rabble. The resurrection men are daring and desperate, it is true, but they are not without their own grievances to complain of: to beat one of them to death, or shoot him, if caught near a churchyard, is nothing; it is supposed to be perfectly fair—quite good in Irish law; while any reprisal or proportionate reaction is magnified into a horrible crime, the press fumes, and the public are roused up. Such is no exaggerated account of the present state of things in Ireland. And we shall see that the causes are not at all difficult to be assigned. The public odium which attends the practice of anatomy is, in fact, owing to dissection being made

part of the punishment of murderers. Dissection is abhorred by the Irish public, as well as by the British, because it is performed on executed criminals; and dissectors (and by implication, of course, the whole profession) are unpopular, because they are the operators in the detested process. Any thing done to the dead body, by way of insult to the memory of the deceased, has ever been and must be odious in public estimation; the association is perfectly natural. Thus the burying of highwaymen and house-breakers at the cross roads—the interment of suicides out of consecrated ground—the practice of driving a stake through the body—gibbeting, and so forth, have ever been looked upon by almost every class with horror; and not less in Ireland, we may be sure, than in other countries, where superstitious feelings and the passions have so full a scope. Need we then describe how offensive dissection must appear to all who recollect that it is ordained by law as a *punishment* for the dead—the ignominious dead? Insult and vengeance are the spirit of this law, unless indeed we add, that it is also intended to strike terror into the living. As a means of instruction to the schools of anatomy, it is quite superfluous; in Ireland, particularly so, where of all countries it could best be dispensed with, insomuch that there it must assume the character of wanton outrage upon the dead. And if such be the feeling with which they contemplate the deed, how may we suppose they look upon the doers? As they do upon Jack Ketch, or on his not less disreputable coadjutor, the decapitator of Thistlewood.

There is one more mistake in Mr. Guthrie's statement, which we should be glad to set right before we have done. He speaks of the Dublin anatomists as "actually selecting the bodies of murderers, not only seeking them for dis-

section, but publishing, in the face of the whole country, the experiments performed on them." This "actual selection" is an unguarded expression. Those bodies are *accepted*, necessarily, and perhaps willingly, but they certainly cannot be said to be *selected*, or taken in preference to other subjects, for the purposes of public dissection; and that for a very obvious reason, inasmuch as no other bodies, save those of executed murderers, *can* be publicly dissected. And as to the publishing of the experiments on those occasions, this too can hardly be otherwise; it is done more through necessity than from recklessness. Public curiosity *must* be satisfied; the transaction is essentially public, and the publication of matters so intrinsically worthless and insignificant is evidently more in consequence of a duty imposed, than of a selection freely made.

LICENSE AD PRACTICANDUM.

IN our last number, page 21, after remarking that the University of Dublin neither grants licenses to practice, nor recognises her graduates as practitioners, we added, "the same ordinance prevails at Oxford and Cambridge:" this was a mistake—a license *ad practicandum* is frequently granted in the former University after taking the degree of Bachelor in Physic; in the latter it may be obtained on going out in Arts, without becoming a Bachelor in Physic.

COLLEGE OF PHYSICIANS,

Monday, April 5.

SIR H. HALFORD, PRESIDENT, IN THE CHAIR.

On the Guaco.

DR. HAWKINS read a communication from Sir Robert Kerr Porter to the President on the subject of the *Guaco*. This is a parasitic plant, a native of South America, and possessing a high reputation in these regions as an anti-

dote to the bites of venomous serpents, the black scorpion, rabid dogs, &c. &c. The evidence adduced in support of these pretensions consisted of extracts from a memoir, published at Santa Fé de Bogota, by Senor Orbeis; and from a paper, by Mr. W. White, on the virtues of the guaco, and the mode of its application, dated Caracas, December 8, 1829. The former states, that when at Maraquito, in 1788, he heard mentioned the extraordinary powers of the native Indians in resisting the bites of snakes, in consequence of which they were called *Empericos*. Determined to judge for himself, he sent for one of these gifted persons, who brought with him one of the most deadly serpents of the country in a calabash. Having offered the Indian a handsome gratuity, he explained to him both the nature of his secret remedy—the guaco, and the mode of using it. He took the leaves and bruised them, extracting two large spoonfuls of the juice. "He then introduced some of the same fluid into three incisions he made between the fingers in each of my hands; also added the same kind of inoculation into my feet, and on the right and left sides of my breast." After this the Senor seized and handled the serpent, which indeed made no attempt to bite him.

Mr. White states the guaco to be efficacious in the bites of serpents, scorpions, and all other reptiles; in hydrophobia, rheumatism, contusions, amenorrhœa, diseases of the liver, external ulcers, tetanus, cramp of the stomach, consumption, and probably gout.

Specimens of the leaf and flower, as well as of the juice, were placed on the table, and it is probable that the plant may deserve a further inquiry into its merits, but at present nothing can be said with certainty, as its patrons, by attempting to prove too much, have thrown some degree of doubt over the accuracy of the whole narrative.

TAPPING IN HYDROCEPHALUS.

DR. CONQUEST introduced to his class, at St. Bartholomew's Hospital, on Saturday evening, one of the two children who have been successfully tapped by him for the relief of water in the

head. It having been previously intimated that the child would be brought forward, considerable interest was excited, and an unusual number of gentlemen were present. This child, a girl of about two years of age, had several signs of hydrocephalus from a date soon after its birth, and for many months past the head had gradually increased, until it acquired an enormous size. The forehead was singularly broad, and the anterior fontanelle unnaturally large. The pupils were permanently dilated; the child slept almost incessantly, and frequently had two or three frightful convulsions during the day and night. Dr. Conquest operated some time since, before a large number of the pupils of the hospital, by pushing a very beautifully constructed trocar into the right lateral ventricle. He introduced it obliquely, close to the edge of the right temporal bone, about midway between the crista galli process of the ethmoid bone and the anterior fontanelle, so as to avoid the longitudinal sinus on the one hand, and the corpus striatum on the other. The instrument entered about two inches below the scalp. An ounce and a half of bloody serum, mixed with portions of cerebrum, escaped. The pulse became feeble, and temporary collapse followed. The fluid was allowed to escape stillicidium, and within eight-and-forty hours about two pints and a half flowed out of the opening. Almost immediately after the operation, the pupils became sensible to the stimulus of light; the drowsiness was succeeded by disinclination to sleep, and the pulse, which had always before been remarkably slow, became about eighty-five. Two days after the operation, the brain evidenced signs of inflammation, with high constitutional disturbance; and great alarm was excited by a rather formidable attack of convulsions. Leeches to the temples, and the constant application of cold to the head, subdued the local inflammation, and within four-and-twenty hours all became tranquil. The head was well strapped, and from the cessation of cerebral excitement no unfavourable circumstance occurred.

When this interesting child was exhibited to the class on Saturday evening, every one was struck with the improvement of its appearance, and by the intelligence and cheerfulness of its countenance. Dr. C. stated that he con-

sidered it perfectly well, and as exhibiting a most gratifying and triumphant proof that this seemingly formidable proceeding might be safely and successfully adopted under similar circumstances.

The other case, to which the doctor has often adverted during the winter, he operated on last autumn, assisted by Dr. Hodgkin, the talented pathologist of Guy's Hospital. Nine ounces of serum were withdrawn from the posterior fontanelle. The head became lessened *six inches* in its circumference, and no increase in its size has yet recurred.

St. Bartholomew's, April 5, 1830.

ROYAL INSTITUTION,

Friday, March 26, 1830.

SIR GIFFIN WILSON, F.R.S. IN THE CHAIR.

Life Contingencies, &c.

MR. BROOKE, who this evening descanted "on the principles of the doctrine of life contingencies," did not appear to us to have developed any new principles, or to have rendered the practical application of those in familiar use either more perspicuous or more comprehensive. Hence we avoid giving an analysis of his observations, which were certainly more fitted for the closet than the lecture-room; and for the various accounts adduced of the respective health and longevity of the inhabitants of different towns, districts, and countries, the influence of political and moral causes, the effects of occupation, &c. &c. on health and life, we must refer to Dr. Hawkins' very valuable work on Medical Statistics, where the subject has been most ably treated. As an instance of the errors which the former modes of calculation involved, Mr. B. observed that an old computation stated that, in the year 1800, London would contain 5,800,000 inhabitants; whereas, by the census of 1801, it appears that the population, one year later, only amounted to 900,000—being a *trifling* mistake of upwards of four millions out of five.

In the library we observed some beautifully preserved Ceylonese birds, sent by Mr. Hume; various geological specimens, also from Ceylon, sent by

Dr. Davy; samples of stone coal; some curious specimens of iron delft ware; a cotemporary enamel miniature of Cowley, the poet, by Pettitot; and Goodwin's scheme for a national cemetery—a very picturesque plan, but, to our mind, a far less *grave* design than the projected London pyramid. Any thing, however, would be preferable to the present indecent system of interment in the streets of London: *e. g.* the churchyards in the Strand, the city cemeteries, *passim*; as well as that burying-ground, the name of which is a very mockery, St. Giles's in the *Fields*.

EXTRACTS FROM JOURNALS,

Foreign and Domestic.

OBSTINATE HYSTERIA CURED BY THE REMOVAL OF A SMALL TUMOR FROM UNDER THE BREAST.

A WOMAN had two small tumors, moveable under the skin, and about the size of small peas, which made their appearance after a blow on the chest. The development of one preceded that of the other, and was not attended with inconvenience. The appearance of the second was followed by symptoms of severe hysteria. She had been in this state for several years; when at length, urged by the severity of her sufferings, she applied at La Charité for relief. M. Boyer extirpated the tumor which had formed last, and thus at once put an end to the disease.—*Gazette Medicale*.

INTERMITTENT HEADACHE CURED BY THE EVACUATION OF CALCULI FROM THE NOSE.

A young woman had periodical headache, returning every day, and apparently originating in the left frontal sinus, and extending all over the corresponding side of the head. After many years suffering, she evacuated from the left nostril a calculus as large as a bean, which event was followed by improvement. She now tried sternutatories, by which means several more calculi were ejected, and afterwards some foetid pus. From this time she got well. The calculi were analysed, and found to consist of phosphate of lime, carbonates of lime, and magnesia; traces of soda,

oxide of iron, and animal matter.—*Ibid*.

SUSPENSION OF THE CEREBRAL FUNCTIONS FROM IRRITATION OF THE STOMACH.

Little more than a month has passed since I was requested to visit a gentleman said to be in a dying state. I found him apparently without sensation, his eyes open and turned up, his hands clenched, and his body alternately motionless and agitated by sudden and universal tremors, which caused the bed to shake beneath him. He was a stranger, and there was no one present who could give me a history of his case. In order to explore into its nature, I placed my hand upon his epigastrium; but scarcely had I touched the skin when he started up as though a bullet had been driven through him. Uncertain whether the coincidence might not be accidental, I repeated the experiment several times, and at each time the slightest pressure was sufficient to throw the whole frame into immediate and violent, though brief convulsions. Sufficient evidence was thus afforded of the seat of the disease, but not of the precise nature of the irritation. As his pulse was active, I bled him freely, and immediately afterwards applied a large sinapism over the region of his stomach. Consciousness was so far restored a few minutes after the bleeding, that, upon being asked in a loud voice if he felt sickness or pain in the stomach, he nodded in the affirmative. An injection of assafoetida was now administered; and, under the united influence of this remedy and the mustard plaister, he revived to some knowledge of his situation, and was able to drink very freely of warm water, which I urged upon him. This soon produced the discharge of a considerable quantity of acid liquors from his stomach, and restored him for a time to complete consciousness. He now told me that he was subject to gout, of which he had recently had an attack in his foot, but had relieved himself by bathing the affected part with hot vinegar. The nature of the case was evident. While he was yet speaking, he was seized with a sudden spasm of the stomach, which threw him into his former state; and this alternation of consciousness and insensibility was repeated several times within the course of a few

minutes, each return of pain being so severe as at first to throw the whole nervous system into violent agitation, and then to overwhelm it for a time in complete torpor. I now applied sinapisms to the feet, and gave a mixture of laudanum and the aromatic spirits of ammonia; and, at the end of about four hours from the commencement of the attack, left my patient very greatly relieved. A dose of the compound tincture of rhubarb, with a proper regulation of the diet, was afterwards sufficient to complete the cure.—*Dr. Wood—in North Amer. Med. and Surg. Journal.*

PRESSURE ON THE DIAPHRAGMATIC
AND PNEUMO-GASTRIC NERVES SIMULATING
DISEASE OF THE HEART.

A female, aged sixty, had for many years experienced pain behind the sternum and at the lower part of the chest, which occurred in paroxysms. The pain was at first slight, but augmented in intensity, preserving however its intermittent character, and became soon accompanied with violent palpitations of the heart, difficulty of breathing, œdema of the upper extremities, a small pulse; and in a word, all the symptoms indicative of an obstruction to the circulation through the superior extremities. This patient remained for two years in La Pitié, during which time her chief complaint was of the pain behind the sternum, and at the lower part of the chest. For a long time she had no appetite; the emaciation was extreme, and she spoke in a whisper. At length she died.

On examining the body, it was discovered that the pneumo-gastric and left diaphragmatic nerves, as well as the aorta and its branches, and the veins of the superior extremities, were surrounded in different parts of their extent by masses of a schirrous nature, by which they were compressed, but not disorganized. The heart, which was of its ordinary dimensions, was of much deeper colour than ordinary; its tissues also appeared softened. The lungs were healthy, except that the right presented at its summit an excavation filled with blackish blood.—*Bibliothèque Médicale.*

OSSIFIED BRAIN.

M. C. Matteucci having examined a brain which he discovered in an old

anatomical collection, found it to exhibit a singular case of ossification throughout its whole substance. When heated, it burnt, evolving ammonia, leaving a bulky charcoal. When examined by chemical agents, carbonate of lime was found in small quantity, and phosphate of lime in much larger, but the principal part of the mass was animal substance, closely allied to *osmazome*.

The composition of the concretions that are sometimes found in the pineal gland, are, according to Fourcroy, of the same nature.—*Ann. de Chimie*, xlii. 335.

EFFICACY OF THE ESSENTIAL OIL OF
LEMONS IN SOME DISEASES OF THE
EYES.

M. Werlitz cuts a slice of lemon-peel, about an inch long and half an inch broad, places the upper part opposite the affected eye; and the eyelids being opened, squeezes out the little drops of volatile oil contained in the tissue of the rind into the eye. The sensation produced is acute, and continues for an hour or two. If the pain caused should be severe, cold applications are to be employed. The effects attributed to the oil of the lemon-peel are those of increasing the capillary circulation, and causing the absorption of morbid depositions.

From experiments which have been made at Berlin, it would appear that the following diseases are remedied by this treatment: 1. Inflammations of the eye which are passing into the chronic state, and which affect the external parts, as the conjunctiva, cornea, or sclerotic, particularly if the small vessels be turgid. M. Werlitz has also found the remedy useful in the rheumatic, gonorrhœal, and scrofulous forms of ophthalmia; in pannus and pterygium; in albugo, and opacity of the cornea; and in cases where the texture of the cornea has lost its healthy density, and becomes soft and spongy. The remedy may be employed frequently during the day, depending upon the degree of irritation it produces.—*Journal für Chirurgie und Augenheilk.*

ANEURISM OF THE ARTERIA INNOMINATA,

Involving the Subclavian and the root of the Carotid, successfully treated by tying the Carotid Artery.

By VALENTINE MOTT, M. D.

Professor of Surgery, New York.

—

MOSES R. GARDNER, æt. 51, by profession a farmer, of sound constitution and good habits of life, applied to me some time in March for advice.

He gave the following relation of his case:—About three years ago, while occupied in removing a building, and compelled to lift heavy weights, he was attacked with pain in the upper and back part of the neck. This lasted until the month of January, when it extended to the right shoulder and arm, and continued until the following May; it then partially subsided, and he observed his voice was becoming hoarse, which he attributed to exposure and consequent cold. About eighteen months since, while shaving, he discovered a small swelling at the upper part of the breast bone, but did not remark any throbbing in it until some time afterwards. He had consulted a physician, but received no positive opinion on the case.

Upon examination, I found above the sternum a pulsating tumor, about the size of a pigeon's egg, spreading some distance under the clavicular and sternal portions of the right sterno-mastoideus muscle, in the course of the subclavian artery, and extending as low down upon the pleura as the second rib, compressing more or less the bronchial tubes, and producing, on the least coughing or exercise, a wheezing, not unlike that of asthma. He shrunk from the least pressure upon it; complaining of impeded respiration, followed by pain. Its pulsations were synchronous with those of the heart, and decidedly aneurismal.

After fully explaining to him the nature of his disease, and its probable fatal termination should it increase and be left to itself, I advised him to return home; to avoid all exertion; to be occasionally bled, and to confine himself principally to a vegetable diet; but should he observe the least increase either of the tumor or any of his symp-

toms, to come again to me, and I would decide on the propriety of an operation.

I thought further delay unnecessary, and he being willing to abide by my judgment, after having stated to him the chances of the operation, I resolved on its performance. From the evident interruption in the circulation of the right arm, and the apparent effort of nature to effect a spontaneous cure, I determined upon tying the carotid first, to observe the result, and afterwards to secure the subclavian, should it be required.

On the 26th of September I operated. The artery was taken up in the usual manner; no material change was observed.

27th.—9 A. M. Slept well, and feels refreshed; thinks there is more room, as he expresses it, in breathing; complains of a little soreness of the tonsils in swallowing; pulse 58, regular, and tranquil; skin natural, pulsation and size of the tumor evidently diminished. 9 P. M. Much more restless from mental alarm; pulse 68, tense. In other respects the same as in the morning; being habituated to laudanum, was permitted to take a tea-spoonful.

28th.—9 A. M. Slept well after the opiate; breathes easily, and says he takes "a more satisfactory breath" than he did before the operation; feels much less of the pulsation in the tumor; pulse 63, not so tense; skin natural; cough much less. Ordered a dose of calcined magnesia and Epsom salts. 9 P. M. Has passed a comfortable day; his wife, who arrived from the country since the morning, expressed her surprise at the improvement in his voice and breathing, and the difference in the beating of the tumor. Pulse of the right radial artery very distinct, but intermitting once from ten to fifteen beats; in the left arm 80; coughs frequently, and expectorates freely; skin natural; tongue a little white; salts have not operated. Ordered the dose to be repeated, and if restless after its operation, to take his usual anodyne.

29th.—Saluted me this morning upon entering his room, with a full and fine voice, and said he was well enough to call on me; salts operated freely; thinks his cough and expectoration much less. I found him lying down and breathing quietly; pulse 71, and regular. The radial artery of the right arm beating as

last evening, with fewer intermissions, but of longer continuance; skin over the tumor more wrinkled; pulsation appears less, and feels weaker. Directed to continue his tea, toast, and gruel. 8 o'clock. As well as in the morning; takes a full breath without the least wheezing; pulsation in the right wrist very distinct and regular; in the left 62 to the minute. Continues the opiate.

30th.—Found him lying more recumbent than at any former period; pulse 70, and regular; right radial artery does not beat quite so firm as yesterday; wound discharging a little, was dressed.

October 2d.—Says he now feels as if he would get well; cough rather more troublesome; pulse 57; pulsation of the right radial the same; his bowels not being free, directed sub. mur. hydr. grs. viij.; sup. tart. potassæ, pulv. jalapæ, aa. ʒj. M. Evening:—Medicine has not operated; directed a dose of sulphate of magnesia. * *

16th.—Ligature separated and came away last night; the tumor above the sternum and pulsation entirely disappeared; cough and breathing better; voice nearly natural; pulse 66; now and then a very faint pulsation of the right radial artery; right hand a little swelled, and feels numb, and complains of the want of power to close it. * *

26th.—Left town this morning for his residence in New Jersey.

New York, Dec. 8, 1829,
25, Park-Place*.

HOSPITAL REPORTS.

LONDON HOSPITAL.

Disease of the Heart after Rheumatism.

[Case of Joseph Howard, continued from p. 735,
Vol. V.]

MARCH 1st.—Is much worse this morning, but does not complain of pain; is troubled with sickness and vomiting, for which he has had the mist. effervesc. Dyspnœa increased. Bruit de soufflet and bruit de scie have of late been very distinct at the upper part of the chest. Pulse 120, and throbbing.

Perstet.

2d.—Says he feels better to-day. Respiration is more oppressed. Pulse 96, full and soft; less cough; feels his throat sore, but not his gums; lips rather purple; tongue

white; skin natural; one or two motions daily.

Perstet.

3d.—Feels much worse to-day; dyspnœa very great; pulse 120.

Perstet.

5th.—Dyspnœa increased; less cough.

To have Cerevisiæ Oss.

Perstet.

9th.—More tendency to orthopnœa.—Pulse 120; tongue dry; says that he has not strength to cough; mouth not sore.

Pulv. Digitalis, gr. i. o. n.

11th.—He died this forenoon.

Post mortem Examination on the 12th.—The body was much emaciated; the face of a leaden hue.

On percussing both sides of the chest previous to any examination, the right side was found to emit a much clearer sound than the left; and on exploring the chest, by introducing the perforator* above the margin of the eighth rib of the left side, fluid escaped, in a sufficient quantity to point out the presence of hydro-thorax.

On opening the chest, the left side was found to be filled by a straw-coloured fluid, containing flakes of coagulable lymph. On removing the fluid, which was about five pints, a very thick layer of coagulable lymph covered the pleura costalis, and still more abundantly the pleura pulmonalis. A very small quantity was found on that portion of the membrane which is reflected on the upper surface of the diaphragm. The lung of this side, which extended nearly to the diaphragm, was compressed and confined to the side of the spine, and on being handled did not afford any crepitation; it had no appearance of organic disease. The lung on the right side was healthy.

On opening the pericardium it was found to contain about an ounce of limpid serum; and this membrane, on its internal surface, presented several thin and very delicate patches of effused lymph, but no adhesions.

The heart and lungs being removed from the body for a more minute examination, an aneurism was found to occupy the concave side of the arch of the aorta, formed by a dilatation of the outer coat of the vessel, and presenting a circular opening of two inches in diameter. The aneurismal tumor is about the size of an orange, and is filled by a firm coagulum; it extends more to the left than to the right side, compresses the

* An instrument which has been invented by Dr. Davies, of the London Hospital; in shape, like a large needle, with a groove on one side; and which, on being made to penetrate the chest, allows the escape of a quantity of fluid, sufficient to indicate the existence of hydro-thorax.

left bronchial tube, so as scarcely to allow the passage of the handle of a small scalpel, and it also presses on the left pulmonary artery. On making an incision through the most prominent part of the tumor down to the coagulum, it appears that both the inner and middle coats of the vessel have given way.

The aorta is diseased and very much dilated between the aneurism and the heart; and under the internal coat of the thoracic portion (beyond the aneurism), which is rather contracted, there are numerous patches of a fibro-cartilaginous deposit. The bronchial tubes below the seat of the pressure are much dilated.

Abdomen.—A small quantity of serum was found in the abdomen. The liver was gorged with blood. The other viscera were healthy. The head was not examined.

REMARKS.—The case of Howard must be considered as one of no small interest, both on account of the numerous and perplexing train of symptoms, and from the appearances discovered on examination after death.

On the score of diagnosis alone, it is of the utmost importance to fix on such symptoms as may most readily lead to the detection of so insidious and so obscure an affection as an aneurism of the arch of the aorta; an affection which is not indicated with any degree of certainty, by any general or functional signs.

Corvisart put much confidence in the peculiar whizzing at the upper part of the sternum, perceptible by the hand—the dissimilarity of the pulse at the wrists—and the dull sound on percussion; but these are extremely equivocal, and he must have been aware that they could also exist with diseases of the heart alone.

Before the appearance of Laennec's publication, therefore, the difficulties in discovering the existence of an aneurism at the arch of the aorta, and which offers no tumor externally, were found to be almost insurmountable; and the incalculable benefit derived from the stethoscope, in other diseases of the chest, having been admitted, the expectations of medical men were raised high, and great assistance was looked for from the use of this instrument.

The author of Auscultation has brought forward one sign, which enabled him to detect about thirty cases of aneurism; yet,

being still impressed with the great difficulty of the subject, he offers it to the public with much diffidence, as we find by his thus expressing himself:—"Hitherto my experience has been insufficient to enable me to say how far the difficulty of a diagnosis is likely to be removed by the use of the stethoscope*."

The sign (the justness of which he had two opportunities of verifying by dissection) is a pulsation of the aneurism perfectly isochronous with the pulse at the wrist, and in general louder and with greater impulse than the mere contraction of the ventricle. The importance of this sign was so strongly felt by Bertin, and which was verified by him in several instances, as will be seen in his work on the Diseases of the Heart and Arteries, that he stands boldly forward and advocates the use of the stethoscope, as affording the best means of detecting an aneurism of the aorta.

On the admission of the patient whose case we are now considering, an aneurism of the aorta was suspected from the impulsion, and from the bruit de soufflet, and sometimes the bruit de scie, heard at the upper part of the sternum; joined to the circumstance of the patient having attributed his illness to an effort in raising a weight. Little assistance could be afforded by the single pulsation just alluded to, as the dilatation of the artery between the aneurism and the heart gave rise to an indistinct whizzing and pulsation before the blood actually reached the aneurism. Can this single pulsation, then, be confidently relied on in all cases? It is to be feared not; for should an aneurismal tumor be so situated as to be in contact with either of the ventricles or the auricles in a state of hypertrophy, it is *à priori* to be presumed, that, independent of the pulsation of the tumor, an indistinct pulsation would be communicated to it by the contraction of the part with which it might be in juxta-position. Experience and careful observation must alone either refute or confirm the correctness of this sign afforded by the stethoscope; and admitting at present its value, the signs which may be principally relied on in diagnosing the presence of an aneurism of the arch of the

* Forbes' Translation.

aorta, are, 1st, a simple pulsation at the upper part of the sternum, and most frequently a little to the right of the median line, isochronous with the pulse at the wrist; 2dly, an impulse at the same part, stronger than is perceptible at the region of the heart; 3dly, the bruit de soufflet, or the bruit de scie, in the same situations, immediately after the contraction of the left ventricle; 4thly, a whizzing or rushing at the top of the sternum, perceptible by the hand; 5thly, an obscure sound on percussion; and 6thly, the appearance of a pulsating tumor.

Thus all the local signs must be taken together, and are chiefly to be depended on. The general and functional signs which are usually present in cases of aneurism, are also equally marked in organic diseases of the heart and lungs, and are therefore of a very secondary importance.

The signs afforded by the percussion and auscultation of the chest are well deserving attention. The sound, on percussing the left side, was dull; on percussing the right, clear. The respiration was puerile on the right, and inaudible on the left; which indicated one of two conditions—either that the lung of the left side was in a state of hepatization, or that fluid existed in the cavity. The probability of the latter opinion was rendered still more likely by the increase of half an inch on the measurement of this side of the chest; such an increase never having been known to depend on the hepatization of the lung. At different periods, as was noticed in the reports, a very indistinct respiratory murmur was sometimes heard on the left side, close to the spine of the vertebra and down to the lower part of the chest. On the examination this was accounted for, by finding the lung compressed and adhering along the spine; this organ being in general, in cases of considerable effusion into the chest, forced more towards the upper part of the chest.

After several examinations, it was at last mentioned, in the report of the 27th Feb., that doubtful pectoriloquy was heard at the upper part of the left lung; and there was considerable difficulty in accounting for this sign. By Laennec it is pointed out as a pathognomonic sign of a tubercular excavation; but in the present case it was impos-

sible to admit that any such cavity did exist, as the patient had expectorated only a little mucus, and did not present the usual marked symptoms of phthisis. It was at last attributed to a dilatation of the bronchial tubes; although it was at the same time that the articulation of the voice up the tube was too distinct to come within the signification of the term bronchopony, as it is given to us by the celebrated writer on diseases of the chest. It will be seen, by referring to the post-mortem examination, that the principal bronchial divisions were much dilated, and also forced against the upper part of the chest, from the pressure of the fluid. Thus we have a cause, rare it is true, giving rise to pectoriloquy, and entirely independent of any tubercular excavation. There cannot be any doubt as to the existence of the sign, for the voice was heard to be distinctly articulated on traversing the cylinder, by several of the gentlemen attending the clinical practice of the hospital. Had the small instrument invented by Dr. Davies been used, the most certain demonstration of the presence of fluid in the chest would have been afforded, and the operation of paracentesis thoracis been proved feasible. But the attendant physician stated that there was too much evidence of organic disease to expect any ultimate benefit from the operation; besides that, the patient being so much debilitated as to be liable to syncope even on turning in bed, it is not improbable that the abstraction of the fluid (as has been observed in similar cases) would have given so great a shock to the system, and produced such an exhaustion of its powers, that death would have speedily followed. It may here be observed, that, with the excellent signs pointed out by Laennec, and the application of Dr. Davies' instrument, which may be used without the least risk of danger, effusions into the chest can be detected with the greatest certainty; and we may with confidence recommend this little instrument to the notice of medical men.

LECTURES ON SURGERY,

Delivered at St. Bartholomew's Hospital,

BY WILLIAM LAWRENCE, F.R.S.

— 1830 — 40

LECTURE XXXI.

DISEASES OF THE CELLULAR SYSTEM.

Phlegmon—Boil—Carbuncle—Anthrax—Anasarca—Œdema—Phlegmasia dolens.

THE cellular system, gentlemen, which we also call cellular membrane, or cellular substance, constitutes the frame-work of the body; it is the basis of all the organs, except perhaps the hair and the cuticle. Hence you may expect that the diseases of which this system is capable will be met with, more or less, in all the several parts into the composition of which it enters. It is probable that the cellular system is essentially the seat of inflammation, suppuration, serous and other kinds of effusion, and of those several organic changes which lead to the formation of tumors of different kinds.

Now, although the cellular system enters into the composition of all the organs, they do not all possess it in an equal quantity or bulk; therefore those changes—those morbid affections of which this tissue is susceptible—do not take place with equal frequency and facility in all parts of the body; and if there be any structure respecting which we entertain a doubt whether the cellular texture enter into its composition, we find it equally doubtful whether such part be liable to the diseases that I have just mentioned. Perhaps the cartilages are in this predicament.

The Latin word *phlegmon*, which is derived from the Greek term *φλεγω*, to burn, denotes an inflammatory swelling situated under the skin. In fact, *phlegmon* is an acute inflammation of the cellular and adipose cellular tissues, which very commonly ends in suppuration; and the abscess thus formed

is called *phlegmonous*. I have not any occasion to describe this affection now, because I selected it in order to exhibit to you the nature of inflammation generally. I spoke of the phenomena of inflammation, when in this state, as exhibiting a kind of type, from which a general notion of the inflammatory process might be derived. I shall therefore say nothing more respecting the nature and treatment of *phlegmon*, which, in its origin and essence, is simply inflammation of the cellular and adipose tissues. The cellular and adipose tissues may be inflamed so as to constitute a tumefaction, without the skin participating in the disease; that is, when the deeper parts of the system are the seat of inflammation. It is from the active form that the symptoms assume in this acute inflammation of the cellular tissue, that the term *phlegmon* has passed into common use, as equivalent to acute or active inflammation; although, originally, *phlegmonous* as an adjective, could only denote that kind of inflammation which is seated in the particular parts that I have mentioned.

In the case of *phlegmon*, we see inflammation attacking a certain circumscribed portion of the adipose and cellular tissues; it is limited to a larger or smaller extent. But the cellular tissue may be the seat of inflammation active in its nature, and yet not attended with that particular circumstance—viz. the boundary or limit which confines it to one spot. More particularly the stratum of cellular and adipose membrane which is seated under the skin, is liable to inflammation from a variety of causes; and the inflammation, when thus produced, is apt to extend in the cellular membrane (as it is continuous over the body), throughout the whole of the parts in which this texture is developed; it will spread readily through the whole extent of a limb, and reach to the trunk. This is *diffused inflammation* of the cellular structure. It is seated in the same tissue as *phlegmon*; but, instead of being limited to one spot, it wants the circum-

scribing boundary, and it extends in circumference. Now this affection is generally combined with inflammation of the skin covering the affected cellular membrane. I shall therefore defer the observations that I have to make on this part of the affection till I speak of erysipelas, when I shall mention it to you under the head of phlegmonous erysipelas.

Boil and Carbuncle.

The cellular membrane is the seat of other inflammations (and of two in particular), in which the inflammatory process is characterized by induration and the formation of partial sloughs. These two inflammations are *boil* and *carbuncle*; which only differ from each other in magnitude—that is, in the quantity of the cellular system which they occupy. The subcutaneous stratum of adipose substance sends numerous small processes, accompanying the blood-vessels and nerves, into the skin. The blood vessels and nerves that belong to the skin, ramify in the cellular and adipose tissues, and then their branches ascend and pass into the skin itself—those that pass into the skin being accompanied with prolongations of adipose substance; so that, if these textures were dissected minutely, you would find that the skin would appear perforated by an infinity of small openings, which these prolongations of adipose tissue enter. Boil consists in inflammation of one such part of the subcutaneous or adipose tissue. There is a firm but small swelling, of a painful kind, and the skin covering the part assumes a red colour, and presents a pointed projection. The part feels very firm and hard, when you examine it externally, and the inflammatory process embracing the skin, which is a part full of nerves, is attended with very considerable pain; and as this inflammation is seated quite on the surface of the body where the part is liable to be struck or injured, or rubbed, people often experience considerable uneasiness from it. The painful nature of boil is well known, and it has passed into a popular expression—"as sore as a boil." The inflammation does not proceed very rapidly; it will last some days; till at length, on the most prominent point of the elevation, you observe a small yellow pustule formed. The cuticle breaks, and a discharge of a little thick matter takes place; the quantity discharged is not sufficient to produce a subsidence of the swelling, nor very materially to diminish it. This opening enlarges, the discharge becomes more considerable, and you see that a yellow or dirty whitish-looking substance is seated in the aperture. This is the slough of the small portion of the adipose substance which is the seat of the disease. In the course of two or three days, the supuration will have sufficiently detached this

small slough, which then makes its way out through the opening. You see a portion, perhaps the size of a pea, come out. It is a softish loose substance, well soaked with matter. This is what common people call the *core*; and the vulgar, who observe pretty accurately what passes before their eyes, know that the boil will not heal till the core has come out—that is, till this slough of the cellular membrane is separated—and then it will heal very readily. This inflammation very commonly arises from some external irritation of the skin: in persons who have a very tender skin, rubbing or friction, or other external irritation, may produce it. Sometimes a succession of boils forms on the skin after it has been irritated by a blister; more particularly if the blistered surface has been dressed with an irritating application. Or you may have boils formed from some internal cause; and, in fact, there must be some internal cause connected with these occurrences, as it does not often happen that a person has a single boil—one and no more; on the contrary, there is generally a succession; as soon as one is well, another is produced; and thus a person may be plagued with them for several weeks, or even months.

The *treatment* of this affection is simple; in fact we cannot materially control its progress. We are sometimes directed to apply poultices; but people will not usually take the trouble of putting on a poultice for an affection of this kind. The old women say, you should put on a *drawing* plaister, to bring it to a head; and I do not know whether, in this instance, their surgery is not the best; at all events it is the most convenient. You may put on a common adhesive or an ammoniacum plaister, and let it remain till the inflammation has advanced sufficiently to separate the slough; when you take it off the slough comes away with it, and then a common dressing is sufficient to complete the cure. If the boil be large, and give the patient much trouble, a poultice may be applied; and if a succession of them take place, you find it necessary to pay some attention to the person's health—to see that the digestive functions are properly performed.

Carbuncle, as I have already mentioned to you, is essentially the same affection as boil, only differing in magnitude and situation. Carbuncle forms on the trunk of the body, seldom if ever on the extremities, and in a great majority of instances it is found on the posterior surface of the trunk, on the back, the neck and the shoulders (or the interval between them), or on the loins. Sometimes it attacks those parts of the skin where the texture of the integument is the thickest. A very common seat of it is just below the region of the occiput, at the upper part of the neck. I believe we cannot say

that carbuncle will *never* take place on the extremities; in fact, a large boil may be said to be a small carbuncle, and a small carbuncle may be considered as a large boil. It is a question of magnitude. We cannot say that the boil shall confine itself simply to one minute aperture of the kind that I have mentioned, though commonly it does so; in fact, you may have a large part of the cellular membrane involved in the boil; it is, as I have just said, a question of size. We cannot say exactly that a carbuncle is one large boil, but rather that it is an aggregation of boils. It embraces a considerable part of the subcutaneous cellular, and adipose tissues; and therefore includes within its action a great number of those cutaneous prolongations. It is not that the slough is one large one, but a carbuncle consists of a great aggregation of these minute sloughs. A carbuncle begins by perhaps a small pimple, or a little hardness under the skin; it begins in a way from which the patient cannot at all anticipate the serious disease that is to follow. Perhaps he has a little pimple just at the upper and back part of the neck, which feels a little sore, but he does not think much of it for two or three days. In the course of a few days more, however, it will have extended to the surrounding parts, so as to have acquired the size of half an orange, or of the palm of the hand; and if the progress of the affection be not limited, it will soon go much beyond these dimensions. You may have an inflammation on the back, perhaps the size of a large dinner-plate. When it has acquired about the size I have mentioned—that of the palm of the hand—you will find that it consists of an inflamed induration of the adipose and cellular tissue, and an inflammation of the skin covering them. The skin is of a very bright red, generally rough and irregular on the surface, and the subcutaneous tissues are the seat of distention, with induration and irregularity of surface; and under this you feel a hard, solid kind of mass, of uncertain depth—a kind of hard cake of inflamed cellular membrane, which, in circumference, extends considerably beyond the limits of the reddened or inflamed part of the skin. After the lapse of perhaps seven or eight days, the inflamed part of the skin becomes of a very vivid red, and there forms upon the surface of it a number of those minute yellow spots, or pustules, which I described as occurring in the case of boils; and these are in their nature exactly similar. A thick matter escapes from them, which, in the first instance, comes out in small quantities, but which, after the lapse of a little time, exudes much more freely; and particularly if you press upon the part, you find a considerable quantity of matter will issue out of a great number of small roundish openings, in the

inflamed part of the skin covering the carbuncle.

Now you will easily conclude, that if the inflammation of a single part of the adipose tissue under the skin, which occurs in a boil, can be so excessively painful as to become proverbial, the increased inflammation occupying so large a part as that which occurs in carbuncle, will be attended with pain of the severest kind. There is a burning pain, a sense of tension or confinement, rendering it extremely painful to the patient to move that part of the body in which the carbuncle is situated: if it be on the occiput, for instance, it is impossible to move the head or neck. This pain is constant, lasting night and day, and totally preventing the patient from getting rest. It is attended with a violent sense of throbbing and pulsation throughout the whole of the mass; and this painful throbbing is by no means confined to the seat of inflammation, but shoots and extends into the surrounding parts. A local inflammation of this very active and considerable kind, will of course be expected to produce sympathetic disturbance of various parts of the economy. It particularly deranges the functions of the digestive organs; it also disturbs sympathetically the circulating and nervous systems; and thus to the local suffering is added that of serious constitutional disturbance of a febrile character;—and in these cases, between the two, the patient is not only in a state of great suffering and pain, but very frequently he gets into a condition of great danger.

Now if we cut through the carbuncle at the period of time that I have just mentioned, we shall find that there is a very large and thick mass of indurated cellular texture under the skin, which has acquired a considerable degree of hardness; it resists the knife in cutting through it as if you were dividing a portion of brawn. There must, of course, be considerable effusion into the interstices of the cellular and adipose membrane, to produce this brawny hardness. It is a solid and firm effusion, an effusion which has the effect of condensing,—not merely of thickening the part, but of hardening it. Throughout the whole of this dense and brawny texture, there are minute particles of matter disseminated; not a deposition of matter in one cavity, like an abscess, but numerous, and very often small, suppurations, the largest of which will not exceed the size of a pea, and the great majority of which are less. Now when you find matter thus deposited in so many parts in the centre of a hard, tough, unyielding morbid growth, you will easily account for that peculiar sense of tension and confinement which characterizes a carbuncle.

Frequently, in making sections of the diseased mass, you observe parts of the cellular

membrane that have undergone that change which is the precursor of mortification. These have assumed a peculiar yellow appearance. The cellular membrane before it loses its vitality, turns of a dirty yellow colour, and the parts that exhibit that appearance are sure to slough. The minute apertures in the skin through which the matter escapes in carbuncle, increase in size; frequently it happens that the cellular membrane immediately under the skin sloughs extensively, and that the skin covering the sloughing part undergoes the same process, and perishes also. Thus you have a large mortification formed in the interior of the carbuncular inflammation, and this occurrence, which perhaps at the first view to a person who witnessed the progress of an affection of this kind, and was not conversant with its nature, might appear an unfavourable circumstance in the complaint, is the most favourable turn the affection can take. When sloughing thus takes place in the centre of the mass, the detachment of the slough affords an exit for the matter, and will stop the extension of the inflammation in the circumference. The slough which is thus formed is a dirty, loose, ragged, whitish or yellow substance, which comes away soaked with a thick yellow matter. When it separates, a free issue is given to the minute suppurations which are disseminated through the carbuncular inflammation, a clean, granulating surface is produced, and then the parts heal by the natural process of granulation and cicatrization, while the induration and redness subside in the circumference. The sympathetic disturbances which were produced in the economy, are quieted in proportion as the local causes of these disturbances are removed, and the case does well. It often happens, however, instead of taking on this active form, and producing this extensive mortification, that there is a very insufficient discharge of matter through the openings in the skin; in fact, they merely give issue to the suppurations that are seated near the skin, while the deeper seated collections of matter which are dispersed throughout the whole inflamed mass of cellular membrane, are not relieved at all by these openings;—then the inflammation, the induration, and suppuration, which constitute the essence of carbuncle, remain in the circumference, and the disease continues to extend, getting larger and larger, till it attains the size of a plate, or extends as far as the dimensions of the part will allow it. The constitutional disturbance augments at the same time, and you will not be surprised that the powers of the patient give way under such an extension of this formidable disease, and that in fact carbuncle from these circumstances is very often fatal.

I think that the situation I mentioned,

immediately behind the occiput at the upper part of the neck, is perhaps the most dangerous one for a carbuncle to occupy. The head generally participates very seriously in the inflammatory disturbance which takes place when a carbuncle is in that situation, and thus it has happened to me to see several instances of carbuncle thus seated terminate fatally, in spite of all the efforts that could be employed. When it is seated on the shoulder, back, or loins, we generally succeed in checking the progress of the affection.

The causes of carbuncle are essentially similar to those of boil. It very commonly arises as the immediate result of external irritation; blisters, issues, setons, tartar-emetic ointment, plaister of any kind, or any other considerable irritation of the skin, may lead in persons of particular constitutions, and under a certain state of health at the time, to the occurrence of this carbuncular inflammation. Not long ago I saw a gentleman who had a large carbuncle at the nape of the neck, in consequence of having had an irritating plaister applied there. He had consulted a medical person for a pain in the head, who prescribed different remedies for him; among these was a plaister to the neck, to which was added some tartar-emetic powder. He was directed to keep it on for a certain time, and as he was in the habit of following the instructions of his medical attendant, he kept it on, although it gave him great pain. When he came to me, I found that he had got a large carbuncle on the back of the head and neck: he got well of that, but he had another form over one of the scapulæ—this was also cured. It is well for you to be aware of these occurrences, because in elderly persons, and in those of impaired constitutions, you should be cautious how you apply irritants of this kind to the skin, and allow them to remain for a considerable length of time. We must not, however, consider in these cases that carbuncular inflammation arises simply from irritation applied to the skin; we must also take into view the state of the constitution of the individual in whom the occurrence takes place. Now the patient whose case I have just mentioned was a young man, not more than forty-five, but he had been in the habit of living freely, and drinking a good deal of wine, which had done his constitution little good; but otherwise he was not much out of health.

Carbuncle commonly takes place in free livers, particularly those who have been addicted to drinking, and have more or less impaired their constitution by such habits of indulgence; it chiefly occurs in those persons after the middle life, when the effects of such habits are more serious on the health and constitution; in such individuals it frequently comes on after they have been labouring for some time under impaired health. We find when carbuncle has taken place, that

the person recurring to the state of his health, says he has been unwell for some weeks or months—that he has had headache, and been thirsty—that his bowels have been confined—and that his appetite has not been so good as usual.

Now you might naturally expect that local means, particularly the loss of blood, might lead to the resolution of the carbuncular swelling, or might tend to prevent its increase. It is, however, a kind of inflammation which does not admit of being materially checked by measures of this kind. I would not venture to say that the application of leeches for the instant may not have some effect in diminishing the swelling and checking its progress; but I cannot say that I ever saw an instance in which it produced resolution of the tumor when once the carbuncular character was fully established. I cannot, therefore, recommend this course of proceeding with any confidence as to its power in preventing the occurrence of the disease, or, in fact, in hindering it from proceeding to its full development. There is, however, a mode of local treatment which is fully effectual in relieving the patient at the moment, and preventing the further progress of the disease, at least in a great number of cases. This consists in making a free incision through the whole of the inflamed cellular texture and skin covering it; which incision produces a considerable discharge of blood from the parts, and thus no doubt you relieve the local inflammation—you set at liberty the parts which had been in a state of inflammatory tension, and thus you give immediate ease to the patient. After the performance of this incision, which by the way is very painful, from the parts being in such a sensible state, the patient generally feels easy, and you relieve a condition of the greatest suffering. This incision has the further effect of giving a free issue to a great number of the suppurations that are disseminated throughout the carbuncular mass. Thus it tends to circumscribe the disease, and to prevent the inflammation from extending in circumference. General experience has so fully established the benefits of this plan of treatment, both with respect to its influence in relieving the sufferings under which the patient labours, and in preventing the extension of the disease, that it is now considered an universally admitted practice; and a person might be regarded as extremely ignorant if he omitted to adopt this treatment to its fullest extent in carbuncle. Now you must proceed boldly in this incision; for if you only make a small opening to let out the matter, as you would under ordinary circumstances, you might as well do nothing at all. You must cut through the whole length and the whole depth of the inflamed part; and in doing this, you will sometimes have to make

your incision from two to three inches in depth. You must go so completely through it as to cut quite to the base of the cake in the cellular membrane, otherwise you do not accomplish the purpose. If it should require an incision three or four inches deep, it is of no consequence; you must make it; in fact there is no risk of injuring any vessels of consequence, for you do not go deeper than the cellular membrane. In truth, the cellular membrane, in consequence of the induration and swelling, is much augmented and thickened; so that you go no further than the depth of the adipose and cellular tissues; you do not divide any vessels that are beyond the stratum of fat and cellular substance. It is true that sometimes very free bleeding will take place from these incisions; and, in consequence of the indurated state of the substance which surrounds the bleeding vessels, they do not retract—so that you cannot so completely rely on the spontaneous termination of hæmorrhage, as in other circumstances. It is necessary, therefore, to bear this circumstance in mind, and not to leave the patient, after an incision has been made into a carbuncle, until you are satisfied that no hæmorrhage of a serious kind can take place. I remember attending a gentleman who had a carbuncle—an elderly man, about 60. He had a carbuncle on the back of one of his shoulders, which I treated by incision, and he got well. He then had a carbuncle at the back of the other shoulder—a larger one—and he did not like to go through this discipline a second time; however he had no choice, the incision was made, and this also got well. I took my leave of him one day, considering he was perfectly well, and I did not mean to see him again. I think it was next day, or next but one, that I was sent for again; he said he had got a swelling under the arm, and upon examination I found a considerable swelling in the axilla. I thought I felt fluctuation, and feared that matter had formed, I was puzzled to conceive how there should be a collection of matter in this gentleman's axilla so soon: only the day before, or at most forty-eight hours, he was not affected, or he had concealed the existence of the complaint. However I was so satisfied that there was matter, that, although the parts were not very hard, I suspected there might be a carbuncle, and I made a deep incision and let out a large quantity of matter, with which also there came out a very considerable slough of the cellular membrane. The parts over this were thickened and tough, and there was a considerable depth divided. After the matter had come out, there was a pretty free bleeding; and upon looking at it, it appeared to me that it was arterial blood. However, I brought the edges of the incision together, and confined them by sticking-plaster; the blood then ceased to flow: and I

fancied I had managed it very cleverly. I left the patient, and went out to dinner. I dined at a tavern that day; and in the middle of dinner, a young man came in great haste and said his father was dying—that, in fact, it was of no use for me to go, for he would be dead before I could arrive. I did go, however, forthwith; it was some distance—in fact at Pentonville; and when I got there, I found he was considerably reduced by bleeding, and had fainted, which had excited the alarm and idea that he was dying. On examining the axilla, I found that there was free arterial hæmorrhage from the part; but at the same time it was so deep, that I could not satisfactorily find out the bleeding vessel. I tried, in this case, a mode of stopping hæmorrhage which has been confidently recommended as capable of arresting it in all cases where the artery divided is not of large size—namely, a saturated solution of alum. I dipped some lint into this, and confined it in that situation, but it had no effect whatever, and the bleeding went on; at last I was obliged to stop it by getting a large curved needle and ligature, passing them through the skin above where I had made the opening, carrying them through the whole thickness of the tumor, and bringing them out again lower down. I tied a large mass together, and in this way stopped the hæmorrhage.

In the case of a moderate-sized carbuncle—say the size of half an orange—you should cut it straight across, and then longitudinally, so as to divide it into four quarters, and that will give a sufficient issue to the matter and sloughs; only mind, let me again tell you, that you must go deep—through the whole depth of the inflamed substance. You must begin beyond the limit of the inflammation at the commencement of the incision, and go beyond it at the termination, so as to insure that you have included the whole; you will thereby prevent further mischief. But when the carbuncle is large—for instance, when it extends from ear to ear—the crucial incision is not sufficient. You may make the incision the whole length, but then you must make three or four, or more, longitudinal cuts; or you may make a kind of stellated incision, the various cuts meeting in the centre, only take care that you have divided to a sufficient extent the indurated and inflamed mass, so as to give as free an issue as you can to the numerous suppurations that are disseminated through it. After you have done this, you may apply a linseed poultice to the part for one dressing, and then, as your object is to excite and bring on free suppuration, you should dress the incisions you have made with the yellow basilicon ointment, spread thick upon lint—have it spread thick the whole length, and lay it into each of the incisions the whole depth;

then cover it over with a linseed poultice. This excites suppuration, tends to bring the complaint to a crisis, and to prevent it from extending in circumference. This is the essential part of the local treatment of carbuncle; but with this you find it necessary to combine some general means—usually a moderate antiphlogistic treatment is proper: active purgatives in the first instance, then occasionally a repetition of milder ones, with perhaps saline medicines, sudorifics, and low diet. You pursue these means till the local and general excitements are lessened or removed. You may find, particularly in elderly persons, in whom carbuncle chiefly occurs, that a state of feebleness or debility will come on before the local complaint is healed; you find the patient, perhaps, after a time, in consequence of these occurrences, with a weak pulse, and other symptoms of depression. Under such circumstances, you must administer tonics, particularly bark, and give a good diet, with wine. I beg, however, to caution you against the idea frequently entertained of its being necessary to employ these means—that is, tonics, wine, and full diet, in the treatment of carbuncle *generally*—because this comes on in persons accustomed to free living, because the patients have been in the habit of taking a pint or a bottle of wine a day, and because the local mischief frequently ends in mortification. From these circumstances the idea has arisen that debility constitutes the essence of the complaint, and therefore that the general treatment should consist in tonics and a stimulating plan. This is a very mistaken notion, and in cases of this disease where you employ tonic medicines, wine, and full diet, at the latter period of the complaint, it is necessary, as in all other instances, that you should watch their effects, and take care that the patient does not carry them too far, nor continue them beyond the necessities of the case.

I attended a gentleman with a carbuncle lately. It was seated on the outside of the neck, just beneath the occiput; it was what we might call a carbuncle of moderate size. It had been partially opened before I saw it, but not so as to give effectual relief. I just made a crucial incision through it, and it was attended with immediate relief of all the symptoms, and the patient went on very favourably. Now this gentleman was fond of his wine—indeed he took from a pint to a bottle a day, using but little exercise. He was, therefore, very anxious to get to his wine and porter; in fact, persons are haunted with the fear of weakness and being too much debilitated, and they pester medical men to allow them to take something to support them. This gentleman had a good appetite, and could have relished his wine; and really sometimes one is prevailed upon to comply with such requests, though it be

against his better sense: patients are so importunate, that one allows them to have what they want. One day I told him that he might take three or four glasses of wine, knowing that he had been in the habit of taking a great deal. I did not see him some days, for he was going on very well, and I left him to his usual attendant. I do not know whether he confined himself to that allowance of wine, but he went to business and caught cold: he had a violent relapse of inflammation—a severe attack of erysipelas, beginning in the neighbourhood of the carbuncle; and, in fact, he was confined a fortnight in consequence of this. He was more severely ill than before, and it was found necessary to bleed him; the blood was strongly buffed and cupped. I believe if he had not taken the wine I allowed him, that he would have gone on uninterruptedly towards a state of health.

I have spoken of this affection under the name carbuncle; but you will often find it described under that of *anthrax*, which is a Greek word, signifying *burning coal*; and the word carbuncle, which we have employed, also signifies a precious stone—a variety of ruby. It seems strange that two such names should be applied to this disease. Those that have employed the word carbuncle, have sometimes divided the affection into what they call a mild or innocent carbuncle, and a malignant carbuncle. Under the head of malignant carbuncle, which by some has been described by the term *anthrax*, they place affections of a sloughing nature—that is, a local inflammation going into a slough, as occurs in the plague, and some other bad fevers. Respecting this malignant carbuncle or *anthrax*, I have nothing to say, because I never saw it; but in ordinary practice, I know only of that kind of carbuncle that I have described to you, and which comes under the head of the innocent or mild carbuncle of those who divide the disease into two species. There are instances of local inflammations going into sloughing, one of which I mentioned under the name of malignant pustule, and which is produced by the direct application of deleterious substances to the skin.

Anasarca—Œdema—Phlegmasia Dolens.

The cellular membrane often is the seat of effusion, either of serous fluid, or of something of a firmer consistence, which produces swelling of the part in which it is found—a swelling which, in the case of serous effusion, is soft and inelastic, so that when you make pressure upon the part, it retains the indentation of the finger—in technical language, *pits* on pressure; but in cases of firmer effusion it is an elastic swelling, which does not retain the impression—does not *pit* on pressure. When effusion

takes place in the cellular membrane of the body generally, it constitutes *anasarca*, or general dropsy. When it takes place in a certain part, and is confined to a particular portion of the body, it is termed *œdema*. *Œdema* is a Greek word; it simply means *swelling*—nothing else.

Anasarca, or general dropsy, usually begins in the lower extremities, and gradually extends from them over the rest of the body; but we see this taking place under very opposite states of the system. There is an anasarcaous effusion connected with an excited state of the circulation, essentially, therefore, of an inflammatory nature. We find a general effusion into the cellular membrane, occasionally accompanied with a full and strong pulse, and with a defective performance of the various excretions, particularly those of the alimentary canal, of the kidneys, and of the skin;—it is, in fact, a state of inflammatory action of the vascular system, in which the excretories which open into the cells of the cellular texture are the seat of disease, instead of any particular organs being affected. Under such circumstances we find it necessary to take blood, to purge the patient, and to employ the antiphlogistic treatment generally; to put the patient on low diet; and after having adopted these means, we often find it advantageous to try the use of mercury, with squill or digitalis, and of nitre and supertartrate of potash, to restore the excretions. In this way we get rid of the anasarcaous effusion, when it is of an active kind. *Anasarca*, or general dropsy, however, more frequently is seen in connexion with those serious organic affections of the viscera, of the chest, or abdomen, which fall under the care of the physician. Here there is a state of weakness as the cause of the anasarcaous effusion; in fact, in surgery we have little to do with such cases. Occasionally, however, we are called to perform a little operation, in order to remedy the effects of the distention of the cellular membrane. The lower extremities sometimes are so loaded with a serous effusion, that the skin is put on the stretch, and seems as though it would burst, and the patient experiences much distress from this circumstance: the penis and the scrotum become the seat of enormous swellings, which sometimes impede the evacuation of the bladder. Here it is necessary to make a puncture, to let the fluid drain off, and partial relief is thus afforded. All that it is necessary to observe respecting this subject is, that it is sufficient to make a single puncture in a limb or part, such as the scrotum or penis, and through that single aperture, if it be in a dependent situation, the whole of the fluid will drain off;—a single puncture, not broader than the blade of the lancet, suffices for this purpose. Sometimes people talk of making scarifica-

tions in anasarcons limbs, and accordingly they proceed to make several cuts, and these of some length. This is unnecessary, because the cells of the cellular membrane communicate so freely, that the fluid will all drain off through one aperture; and when these long cuts are made, it not unfrequently happens that mortification ensues, as we also see take place from another practice—an extraordinary one—that of putting blisters on anasarcons limbs, to draw the water off. I have many times seen mortification arise from that circumstance.

Edema, like anasarca, may either be active—that is, inflammatory, or passive—that is, from weakness, or you may have various intermediate degrees between these. In active *edema* there is generally, or at least frequently, some degree of redness of the integuments, and some sense of heat communicated to the hand; indeed, the patient is aware that the part is hotter than natural. There is a curious kind of swelling which comes under this head—it generally makes its appearance within a short period after parturition, and is called *phlegmasia dolens*. It is an *œdematous* tumefaction of the lower extremity of one side, to account for which has greatly puzzled practical persons and pathologists; but of late years some successful attempts have been made to investigate the nature of this affection. Dr. Davis found in one case, that there was a state of inflammation in the large venous trunks of the limb—that the external iliac and femoral veins were inflamed, and that to a considerable extent. This has led to an examination of limbs affected with this disease, and similar appearances have been found in a variety of instances; and in many cases where tumefaction of the limb has gone to a serious extent, it has been found that inflammation in the principal venous trunks of the limb had existed, and there could be no doubt that the swelling arose from that cause. Dr. Robert Lee has lately shewn how it happens that the veins of the limbs become inflamed after parturition. He has shewn the inflammation of the external iliac and femoral veins to be the consequence of a change which takes place in the uterus, in consequence of the unfavourable state in which that organ and its appendages are placed at the period of parturition. Thus the veins of the uterus become first inflamed, and the inflammation thence extends to the iliac, and then to the femoral vein. This view of the pathology of the affection has led to the proper mode of treating it, which consists in the application of leeches over the tract of the inflamed vessels, and in the repetition of that measure, with other suitable anti-phlogistic means. It is, however, necessary for you, whether in cases of *phlegmasia dolens* or in cellular *œdema* occurring under other

circumstances, to direct a careful examination to the principal venous trunks of the swelled part—make gentle pressure over them, and if you find by the existence of tenderness that you have reason to suppose inflammation exists, you will be led to the proper mode of treatment by what I have above said.

Some time ago I removed the thigh of a patient in this hospital, in consequence of a compound fracture, and I fancy a vein was tied after the amputation, without our knowing what had occurred; however, the stump went on well, and healed, no particular swelling or symptoms of inflammation taking place in it. But what was very singular, the veins inflamed in the opposite limb, and an *œdematous* swelling of an active kind—a tumefaction of rather a firm nature, with redness, heat, and pain of the sound thigh and leg occurred. On following the course of the femoral vein with the fingers, considerable pain was experienced by the patient; and on tracing the saphena, a hard cord-like sensation was communicated, which, with the other symptoms, left no doubt that inflammation had taken place, both in the femoral and some of the larger veins of the limb. The case did well under the treatment I have mentioned—the application of leeches, antiphlogistic means, with diuretic medicines, particularly mercury, squills, and digitalis.

Edema sometimes occurs not perhaps from the direct inflammatory state of the limb, nor any thing we can call weakness, but in consequence of pressure on the venous or absorbent trunks. The pressure of a tight bandage will produce an *œdematous* swelling of the limb below it: general disease of the absorbent glands of the limb, such as the affection of the glands in the axilla in cancer, produces *œdema* of the upper extremity. The pressure of an aneurismal tumor; the pressure of the pregnant uterus on the absorbents and veins of the lower extremities; these are causes producing *œdema* of the limbs, and in fact, *œdema* thus produced cannot be remedied by any direct treatment; it can only be removed when the cause ceases; and in some of the cases that I have just mentioned, we cannot put a stop to the cause at all.

Where a serious injury has been sustained by a limb, such as a bad compound fracture, or a violent bruise, by which the patient has been long confined, and constantly at rest, when he begins to use the limb again, and to put it into a depending position, it is not uncommon for *œdematous* swelling to take place. Under such circumstances the swelling may be diminished, if not removed, by local friction; either by simply dry rubbing, or friction with a simple liniment, and by local pressure to the part through the medium of plaisters, or a bandage applied to it. These means will be sufficient to get rid of

that kind of œdematous swelling which in these cases may be considered as the result of debility. I would only observe in conclusion respecting this point, that we are not to regard the word œdema as indicating the nature of the swelling to which the name may be applied—not to understand that in every case there is a condition of debility producing that serous effusion in the limb which constitutes œdema. Thus you find in many cases that the state of the limb is one of active inflammation, and only in a small number of cases comparatively is it to be considered as a condition of debility.

OBSERVATIONS ON OPIUM AND ITS TESTS.

By ANDREW URE, M.D. F.R.S. &c.

FEW subjects of chemical research are more interesting to medical science than the constitution of opium. The poppy, like every other vegetable, must vary in the quality of its secreted juices, with soil, climate, and season; whence corresponding changes will ensue in the nature of the inspissated product. Did the anodyne and soporific virtue of this medicine reside in one definite principle, chemical analysis might furnish a certain criterion of its powers. It has been pretty generally supposed that this desideratum is supplied by Sertürner's discovery of morphia. Of this narcotic alkali not more than seven parts can be extracted, by the most rigid analysis, from one hundred of the best Turkey opium; a quantity, indeed, somewhat above the average result of many skillful chemists. Were morphia the real medicinal essence of the poppy, it should display, when administered in its active saline state of acetate, an operation on the living system commensurate in energy with the fourteen-fold concentration which the opium has undergone. But so far as may be judged from the most authentic recent trials, morphia in the acetate seems to be little, if any, stronger as a narcotic than the heterogeneous drug from which it has been eliminated. Mr. John Murray's experiments* would, in fact, prove it to be greatly weaker; for he gave two drachms of superacetate of morphia to a cat, with-

out causing any poisonous disorder. This is perhaps an extreme case, and may seem to indicate either some defect in the preparation, or an uncommon tenacity of life in the animal. To the same effect Lassaigne found that a dog lived twelve hours after thirty-six grains of acetate of morphia, in watery solution, had been injected into its jugular vein. The morphia meanwhile was entirely decomposed by the vital forces, for none of it could be detected in the blood drawn from the animal at the end of that period*. Now, from the effects produced by five grains of watery extract of opium, injected by Orfila into the veins of a dog, we may conclude that a quantity of it, equivalent to the above dose of the acetate of morphia, would have proved speedily fatal.

Neither can we ascribe the energy of opium to the white crystalline substance called *narcotine*, extracted from it by the solvent agency of sulphuric ether; for Orfila assures us that these crystals may be swallowed in various forms by man, even to the amount of two drachms in the course of twelve hours, with impunity; and that a drachm of it, dissolved in muriatic or nitric acid, may be administered in the food of a dog without producing any inconvenience to the animal. It appears, however, on the same authority, that thirty grains of it, dissolved in acetic or sulphuric acid, caused dogs that had swallowed the dose to die under convulsions in the space of twenty-four hours, while the head was thrown backwards on the spine. Oil seems to be the most potent menstruum of narcotine; for three grains dissolved in oil readily kill a dog, whether the dose be introduced into the stomach or into the jugular vein.

Since a bland oil thus seems to develop the peculiar force of narcotine, and since opium affords to ether, and also to ammonia, an unctuous or fatty matter, and a resin (the caoutchouc of Bucholz) to absolute alcohol, we are entitled to infer that the activity of opium is due to its state of composition, to the union of an oleate or margarate of narcotine with morphia. The meconic acid associated with this salifiable base has no narcotic power by itself, but may probably promote the activity of the morphia.

* Edinburgh Phil. Journ. vii. 388.

* Annales de Chim. et Phys. xxv. 102.

Hence, though the weight of morphia obtainable from a given variety of opium may by no means represent the total essence of the drug, yet its quantity is most probably proportional to the powers of the opium. But morphia exists in the state of a meconate, and its quantity must be in equivalent ratio to that of the meconic acid. On this principle, a ready mode seems to offer of trying the comparative narcotic powers of different opiums. Let a grain or two of each be dissolved in a little dilute alcohol, and then diffused through such a body of water as will make the liquid nearly colourless. Pour each liquid into a graduated glass cylinder, and add to it a few drops of red muriate (or tincture of muriate) of iron. The characteristic brown-red tint will immediately appear, of a depth proportional to the meconic acid, and equivalent to the morphia present; for the previous dilution with water has been so great as to remove the inequalities of colour in the original spirituous solutions. Let the darker shades be now lightened with water till the tints of the whole be uniform; and the relative volumes of the liquids will afford an approximate measure of the qualities of the several opiums. It is obvious that a double quantity of any given opium will take a double volume of water to bring its meconate of iron to the standard shade. By this means different tinctures of opium may be very expeditiously compared in narcotic power.

I have tried, in this ready way, Turkey, English, and East Indian opium, and have found the results to harmonize sufficiently with their known powers determined by other methods. An improved East Indian opium, of which Dr. Chambers gave me a specimen, approaches by this test very closely to the quality of fine Turkey opium.

The employment of red muriate of iron as a re-agent for detecting the meconic acid of opium, has been frequently resorted to, under different modifications, since Vogel first pointed out the singular sensibility of that acid to the peroxide ferrous salts. I have found solution of acetate of lead, faintly acidulated with vinegar, the preferable re-agent for separating meconic acid, in the form of a meconate of lead, from solution of opium. The slight excess of acetic acid prevents any of the morphia from falling down with the oxide

of lead. Twenty-seven grains of washed, but still impure meconate of lead, may be obtained from one hundred grains of good opium—a result which I obtained both from the Turkey and the above East Indian. By treating this insoluble salt, diffused in water, with the equivalent quantity of sulphuric acid, or by a stream of sulphuretted hydrogen gas, the meconic acid is set free, and may be procured in small crystalline grains by slow evaporation of the filtered liquid. These grains, once concreted, are very difficult of solution in water, and may therefore be washed with this fluid. Of the washed grey-white grains, a solution perfectly colourless strikes a deep brown-red with a drop of permuriate of iron.

Another process for procuring meconic acid has been prescribed. The magma obtained by boiling magnesia in a watery infusion of opium, is to be washed first with proof spirit, to extract the narcotine and resin, and then with strong alcohol, to dissolve out the morphia. The residuary meconate of magnesia is to be digested in dilute sulphuric acid, and the meconic acid is to be thrown down from that solution by acetate of lead. The meconate of lead is to be washed, then diffused in water, and decomposed by a stream of sulphuretted hydrogen gas. The meconic acid is set free and dissolved, and may be procured, it is said, in impure, scaly crystals, by evaporation.

On this process it may be remarked, that the sulphuric acid of the sulphate of magnesia is unnecessarily dragged along, to the injury of the meconic acid; for sulphate of lead is formed simultaneously with meconate, on adding the acetate of that metal to the mixture of the magnesian sulphate and meconic acid; and these two insoluble salts, the sulphate and meconate of lead, afterwards evolve their acids simultaneously to the sulphuretted hydrogen gas.

Whereas, by throwing down the meconic acid by the just quantity of acidulous acetate of lead, washing the precipitate, and decomposing it, either by the equivalent dose of sulphuric acid or by sulphuretted hydrogen, we at once obtain a relatively pure meconic acid.

From the circumstance of magnesia precipitating both the meconic acid and morphia from an opium solution, it may be inferred that meconic acid will form an insoluble compound with magnesia.

But this is by no means the case, for if we heat a solution of meconic acid with magnesia in excess, no meconic acid is withdrawn from the liquid, for it strikes as deep a red, with permuriate of iron, as before the magnesia was presented to it; but acetate of lead separates the whole of the meconic acid from solution or tincture of opium; so that the supernatant liquid occasions merely a faint greenish-brown colour, with red nitrate of iron.

Among the criminal abuses of the diffusion of knowledge which characterize the present times, the administration of opium, or its tincture, concealed in various vehicles, by the lower orders, with the most felonious purposes, holds a conspicuous place. An atrocious crime of this nature was brought specially under my notice, about a year ago, in examining, by desire of the magistrates of Glasgow, the contents of the stomach of a man who had fallen a victim to these murderous devices. Here the laudanum had been largely mixed with strong beer, and was sensible to the smell, in the liquor extracted by the stomach-pump. One portion of that liquor, treated with acetate of lead, afforded an insoluble precipitate, from which an acid, strongly reddening permuriate of iron, was separated by the agency of the sulphuric. Another portion afforded directly, with a few drops of the permuriate of iron, an evident reddish-brown tinge, very different from the drab or fawn-coloured precipitate occasioned in strong beer of the same quality by the same salt of iron. Other experiments were made, which it is unnecessary to detail at present. The chemical facts, joined to a body of circumstantial evidence, led to a conviction of the guilty pair, a man and wife, who were accordingly executed.

* * * *

When opium is dissolved in porter (good London), the detection of the drug becomes much more difficult than when it is dissolved in strong beer; for permuriate of iron produces with porter (lightened with an equal volume of water) nearly the same brownish colour, whether it be used as delivered by the brewer, or mixed with laudanum to the extent of thirty drops in two ounce measures. A very copious grey-coloured precipitate is thrown down from London brown stout by solution of acetate of

lead—nearly as copious, in fact, as from porter drugged, as above, with tincture of opium. And when these two precipitates, washed in filters, are decomposed by a little dilute sulphuric acid, they afford two liquids, which strike nearly the same red-brown tints with permuriate of iron. It is difficult to resist the evidence thus disclosed of the presence of opium in *genuine* London porter. Tincture of hop, diffused through water, becomes, with a few drops of permuriate of iron, a greenish liquid, quite different from the diluted porter treated in the same way.

Porter becomes turbid when supersaturated with water of ammonia, and lets fall a brown sediment, which, collected and washed on a filter, bears some resemblance to impure morphia, but possesses a very remarkable peculiarity: it neither reddens with nitric acid, nor does it suffer morphia mixed with it to be thereby reddened, or at least the redness is merely momentary, and passes, on the slightest heat, into a light yellow shade. This precipitate I shall make the subject of future researches. Tincture of hops, which becomes slightly turbid on mixing with water, is rendered limpid by supersaturation with ammonia.

It might be imagined that bone-black (animal charcoal) would decolour porter, so that the agency of permuriate of iron on its supposed meconic acid might be made more manifest; but this process is at best fallacious; since bone-black, boiled with a portion of dilute solution of opium, deprives it almost entirely of the power of affecting permuriate of iron; while the corresponding portion receives from that salt a deep red-brown colour.

Whenever morphia can be obtained apart, its identity may be determined by decisive characters; the bright red colour imparted by it and its acetate to nitric acid, and the greenish-blue tint to red muriate of iron.

I have not found the tincture of galls the delicate re-agent for morphia, even to $\frac{1}{15000}$ part, which Dublane, the suggester of this test, announced. It affords, with a solution of acetate of morphia, a grey precipitate, which reddens with a drop of nitric acid; but tincture of gall cannot be used where gelatine, and other animal matters, attractive of tannin, are present. Even aided by alcohol, prescribed by Dublane for dis-

solving out the tannate of morphia from the tannates of gelatine and albumen, it will not answer; for Vanquelin tried, in this way, two portions of urine, one which contained morphia, and the other not; and he had the same result from both—because alcohol dissolves a great deal of the animal matter precipitated by the tincture of galls, and thus complicates the experiment *.

Glasgow, Dec. 19, 1829.

CASE OF
ANEURISM BY ANASTOMOSIS,

In which both the Primitive Carotid Arteries were tied.

By R. D. MUSSEY, M.D.

Professor of Anatomy and Surgery in Dartmouth College, Hanover, New Hampshire.

J. PATTEE, aged 20 years, consulted me in September, 1827, respecting a pulsating purple tumor, situated upon the vertex of his head, with a base of about five inches in diameter, and rising an inch and a half or two inches above the cranium. This tumor had existed from infancy, but had greatly increased within the last three years. Upon the apex of the tumor was a sluggish ulcer of an inch in diameter, which commenced two years before, had been slowly enlarging, and which had bled occasionally during the preceding spring and summer, and once to the amount of two quarts, as estimated by his physician.

The left temporal artery and vein, where they pass in front of the ear, presented through the integuments the appearance of a vessel five-eighths of an inch in diameter. This was so prominent in its winding course along the temple, and even to the base of the tumor, that its pulsations could be distinctly seen at the distance of *fifteen* feet. A vein which passed from the tumor down the forehead, was full and prominent, and half an inch in diameter; and when the head was shaved, more than *twenty* arteries running to the tumor were seen actively pulsating, none of which, as they appeared through the integuments, were less than a middle-sized goose-quill.

Curious to know what would be the

effect of securing the large arteries, from which branches were distributed to the tumor, I tied, on the 20th of September, the *left* primitive carotid. The tumor, after the operation, was a little less tense, and less livid; still the active pulsation of the numerous arteries upon the right side of the base of the tumor, rendered it evident that there was an adequate supply of blood. On the twelfth day from the operation I tied the *right* primitive carotid artery. The face was a good deal paler immediately after this operation, but what was scarcely to have been expected, the functions of the brain were not apparently disturbed. There was neither nausea nor faintness; the patient rose from the table, stood up, and while standing put on his vest and coat, and tied on his cravat; he then walked down two flights of stairs, got into a carriage, and rode to a distant part of the village, without feeling the least symptom of faintness, or manifesting signs of inconvenience.

The tumor, which after this operation was daily dressed with a compress and bandage, so as to make slight compression upon it, the compress being kept constantly moist with alum water, progressively subsided, and in about four weeks was reduced apparently to about one-third of its original volume. At this period the tumor became stationary, and in five or six days began very slightly to enlarge; its colour was a little deepened, and a feeble thrill corresponding with the pulse in other parts, could occasionally be perceived in the left temporal artery. These appearances indicating that nothing further was to be expected from the tying of the carotid, astringent applications and compression; I proceeded on the 22d of November, about six weeks from the second operation, to remove the tumor.

This was accomplished by first encircling the tumor by an incision made quite through the soft parts, and then rapidly dissecting away the whole mass from the pericranium. More than an hour was occupied in carrying the knife around the base of the tumor, the whole operation being conducted with immediate reference to the saving of blood. Not more than an inch and a half of the scalp was divided at a time, and immediately upon the division, firm compression was made upon each lip of the

* Quarterly Journal for March, 1830.

incision, while the vessels were secured by ligatures, more than forty of which were applied in going round the tumor. Notwithstanding, however, these precautions, it was estimated by all present, that blood to the amount nearly of two quarts was lost during the operation. The patient was faint, and continued very feeble for several hours. The naked pericranium, in extent equal to about twenty-five square inches, granulated kindly, and in eight weeks the wound was nearly healed. It was some months, however, before the cuticle, through its whole extent, became firm, so as to sustain itself under considerable variations in the state of the circulation. The patient returned to active labour upon a farm the following March or April, has continued it ever since, and has been one of the most athletic and industrious labourers I have seen.

This case is interesting in a physiological view, for at no period subsequently to the operation of tying the second carotid, with the exception of the faintness and debility which occurred from the actual loss of blood on the removal of the tumor, has there been a single symptom of deficiency of blood in the brain. Indeed, at one period, viz. in the spring of 1829, sixteen or seventeen months after the operation, the opposite state seems to have existed; as the patient had a flushed face, accompanied with head-ache daily for two or three weeks, and was not relieved essentially by cathartics. A single large bleeding entirely removed the symptoms.

The engraving represents the appearance of the tumor after the head was shaved, previously to the first operation*.

November 24th, 1829.

ON THE
REMOVAL BY OPERATION OF CERTAIN DEFORMITIES OF THE FACE.

By R. LISTON, Esq.

CASE I.

Five years ago I was consulted by Mr. M. then aged about 16, on account

of deformity arising from the loss of the columna nasi. Of the manner in which it was destroyed he gave the following history:—When at school, about four years previously, in playing at ball, one of his companions accidentally struck him on the face with the palm of his hand; great swelling followed, with

* Amer. Journ. Med. Sciences, Feb. 1830.

obstruction of the nostrils: the case was neglected, and in eight or ten days profuse discharge took place, with diminution of the swelling. The discharge continued for a long time, and was attended with considerable fœtor; some small pieces of bone were thrown out, and at length the columna, the whole of the cartilaginous, and part of the osseous septum, were destroyed. When the patient applied to me, the ulcer had not entirely healed, and the point of the nose was supported by a prop made of wire, covered with oiled silk, which an ingenious dentist had provided him with. His appearance was by no means becoming, and he was anxious to have the deformity removed, if possible. At that time I proposed, so soon as the discharge had ceased, to furnish my patient with a new columna from the upper lip, and had several conversations with him and his friends on the subject. The proposal was, however, not acceded to, and I lost sight of Mr. M. until the beginning of the present year, when I was again applied to. There was now no ulcerated surface observable; it was, however, imagined some slight fœtor could be detected. The decoction of sarsaparilla was given, and a little liniment of citrin ointment and lime water occasionally applied to the nostrils. About the beginning of July, with the advice of Drs. Monro, Abercrombie, and Mr. McKenzie, the operation was performed as originally proposed. The inner surface of the point of the nose was pared; a bistoury was then twice passed through the upper lip, close to the root of the original columna, and each time carried down to the mouth, so as to include a slip of about one quarter of an inch broad. This slip, composed of skin, lining membrane, and interposed substance, was deprived of its prolabium, and attached by a pin passed obliquely through it and the inner side of the tip of the nose, and then secured by some turns of ligature. Two sewing needles, and twisted suture, sufficed to bring the lip neatly together. These were removed in a few days, and the lip, which was before too full, had united perfectly, with considerable improvement to my patient's appearance. Even though, as I had warned him might happen, the other part of the process failed, Mr. M. was now in a better condition than before submitting to the operation; but

the union of the slip was also perfect, and in a few weeks, by supporting it with a small round compress, and by plugging the nostrils, his appearance was totally changed; so much so, that from being constrained by the horrid deformity to confine himself to his house and surrounding grounds, for many years, he has been so metamorphosed that he can now mix in company, without its being observed that any operation had been performed to improve his countenance.

That part of the membrane of the mouth now forming the lower surface of the columna (the lip was not twisted, and thus the chance of failure much diminished) for some time remained reddish, but by exposure to the air, has now assumed the same colour as the surrounding skin.

CASE II.

[From the Journal of the Royal Infirmary.]

Anna Riley, admitted Aug. 10th. There is very copious and fœtid discharge from the nostrils; the triangular cartilage, and columna nasi, are completely destroyed; and the inner surfaces of the alæ nasi extensively ulcerated; the point of the nose has become quite flat and depressed, from the loss of the natural support. Disease is of six months' duration, and commenced without evident cause; she has never had lues venerea, and has never taken mercury.

11th.—Ulcer to be touched with the nitras argenti every second day; alæ nasi, and point of the nose, to be supported with dossils of lint. Meat diet.

18th.—Ulcer healing; discharge less, and not so fœtid.

R S. Zinci $\mathfrak{z}\text{i}$.

Spirit. Lavand. $\mathfrak{z}\text{ss}$.

Spirit. Rosmarini $\mathfrak{z}\text{ii}$.

Aquæ $\mathfrak{z}\text{xxx}$.

Fiat lotio ulceri applicanda.

Oct. 7.—Ulcer has been quite healed for some time past. To-day Mr. Liston performed the following operation:—Having pared the inside of the point of the nose, he made two parallel incisions through the whole extent of the upper lip, on either side of its centre, and separated from each other by a distance of three lines; the mucous membrane having been removed from the free end of the portion of the lip comprehended within the two incisions, was preserved

in contact with the pared surface of the point of the nose, by means of a needle passed through both, round the end of which silk was twisted. The wound in the lip was united by the hare-lip suture.

11th.—The needle through the point of the nose was removed two days ago, and to-day the two remaining ones have also been withdrawn. Both wounds have adhered by the first intention.

On the 13th of October she was attacked with dysentery, from which, by the use of leeches and opium, she had completely recovered by the 21st. The *alæ nasi* since the operation have been supported by lint, and latterly a lotion of the sulphate of copper has been applied.

27th.—To-day she has been dismissed cured, her appearance much improved by the operation: the apex of the nose has acquired its natural prominence, and the new *columna* effectually conceals the deformity arising from the destruction of the septum. The inferior surface of the *columna* still retains some of the characters of the mucous membrane.

—

At one time (and even now a-days by some practitioners) both these patients would have been looked upon as sufferers from their own, or perhaps their parents' indiscretions. Many noses, and parts of them, have been lost, even within my recollection, from the consequences of venereal diseases, or, I should rather say, from the effects of the remedies extensively and indiscriminately employed, and reckoned absolutely necessary for their eradication.

I was consulted lately by a gentleman as to the possibility of improving his appearance. He had, or supposed that he had, about 20 years ago, contracted syphilis; he was salivated till, from the swelling, his features were almost indistinguishable: the discharge was so copious and so long-continued, that he tired conveying a vessel constantly to his mouth, and had one contrived to sling under the chin from his neck. Purulent matter began to flow from his nostrils, and to check it, fumigations were employed. A crust was formed, a complete mould of that part of his features when it separated; the *columna* and cartilaginous septum fell with it.

It is probable that he may yet submit to the modification of the rhino-plastic operation, as above described. Happily the number of persons so disfigured is now much diminished.

The cartilages or bones may suffer from ulceration commencing in the mucous membrane, in consequence of injuries, or irritations of various kinds, as well as from disordered health. I have seen some cases in which ulcers perforating the septum have apparently been kept up, if not produced, by snuff-taking; others which could be traced to the presence of the decayed fangs of the incisors of the upper jaw. In one case a dentist had persisted, notwithstanding fetid discharge, &c. in keeping false teeth over the stumps, a practice which cannot be too much deprecated. But this useful and ornamental part of the face may suffer from the effects of direct injury, as in the first, and probably the second case related. The most common cause of destruction of the partition of the nostrils is abscess in the submucous cellular tissue, generally arising from blows. I have not, in surgical books, met with any notice of collections in this situation.

The first such case which occurred to me in practice was that of a dissipated comedian, who had received (so far as I recollect, from his amiable helpmate) a blow on the lower extremities of the *ossa nasi*. He presented himself to me on the sixth day after the accident, with both nostrils obstructed by bulging of the *schneiderian* membrane of the septum. The tumor fluctuated, was opened on both sides, and a great quantity of pus discharged. A portion of the septum was destroyed, and some deformity ensued. A considerable part of the cartilaginous septum may, however, be removed, without the loss being indicated by any change in the external form of the organ. In cases of abscess, the destruction of the septum can only be prevented by an early opening. I have treated in all seven cases of this disease, and in but one, besides that above related, has the least deformity taken place.

EdinLurgh, March 23, 1830.

A NEW METACARPAL SAW,

INVENTED BY

J. W. CHEVALIER, Surgeon.

A CONSIDERABLE time has now elapsed since I was consulted by a gentleman of rank in this metropolis upon the expediency of removing a tumor, of the size of an orange, which projected over the palm of his right hand, from the remaining stumps of the metacarpals of his little and ring fingers.

He had already submitted to two operations for the same disease, the latter of which took place not less than *seventeen years* ago; and on both occasions it was found to consist of a semi-cartilaginous structure, supported by an arborescent exostosis. It had hitherto caused no further inconvenience than that arising from its bulk.

I found that there still remained a sufficient extent of the metacarpal bones in question, to admit of the removal of the tumor without opening the joint of the wrist; and although the disease in this case would not be eradicated, more especially as it appeared to have attacked already the styloid process of the ulna, yet it would in all probability be rendered innocuous for the remainder of the patient's life; while the valuable use which he retained of the remaining fingers and thumb would still be preserved, and all risk from exposure of a cavity so complicated and important as that of the carpus, would be effectually avoided.

The portion of bone which continued free from disease was, however, so small, that without any question, the ordinary metacarpal saws must have fractured it; or at all events, have rendered it carious, by the violence of their operation. A fourth of an inch in thickness was as much, or more, than I could hope to save between the surface of the wound and that of the perichondrium within the joint; and before this, I had had opportunities of witnessing the havoc that is often created in the hands and feet with those coarse and unsurgical instruments usually employed in such cases.

I therefore contrived a new one, represented in the annexed drawing, and as a considerable number of trials has convinced me of its utility, I think it right to offer it to the notice of the profession, and to recommend its use in cases in which it may be deemed advisable to saw through the metacarpal

or metatarsal bones, rather than to lay open their capsular ligaments. It should be used with a light hand, and patiently; for the smaller the teeth of any saw, the greater the number of strokes which it will require to cut through a given substance.

62, Torrington-Square, April 2, 1830.

Explanation of the Figure.

- A B, a moveable saw-blade, made of watch-spring.

TUMOR IN THE CHEST.

To the Editors of the London Medical Gazette.

GENTLEMEN,

SHOULD you deem the following case sufficiently interesting to merit a place in your journal, you will oblige me by giving it insertion.

I have honour to be

Your very obedient servant,

J. COLLIER,

Memb. Roy. Coll. of Surgeons.

Syston, Leicestershire,
 March 18, 1830.

Henry Ward, aged 7 years, of a scrofulous and delicate constitution, has from infancy been subject to shortness of breathing and slight cough.

In March last he was thrown from a donkey, and fell on the right shoulder. Nothing of any material importance followed, except some bruises of the part, from which he recovered in a few days.

In July following it was noticed that he became much fatigued after any little exertion, as walking, and frequently during the day begged of his friends to allow him to go to bed.

In the early part of September a small tumor was discovered in the situation of the left mamma, evidently protruding forwards from the ribs; it gradually enlarged, and at the close of the year had attained the size of a large orange. At first it was unattended with much pain, but became more so latterly. It possessed a hard feeling to the touch, with very little elasticity or fluctuation. There were three projections in different parts of the tumor, but no consent between them. At the end of February the tumor had become more

prominent in the centre, and at that point felt soft to the touch; a lancet was introduced into it, but only a small quantity of dark blood followed, and portions of fleshy matter.

The integuments covering the tumor were not discoloured. The heart was felt to beat on the right side of the sternum. The glands in the axilla were slightly enlarged.

The constitutional disturbance was great—such as restlessness, difficulty of lying down in bed (the easiest posture was on the left side); cough, without any expectoration; great emaciation; occasional flushes of heat, and perspiration. Pulse small and weak; average rate 100. Appetite sparing. Little was done in the way of treatment except giving him laudanum, to procure sleep, and aperient medicines, with fomentations and poultices to the part. He gradually became worse, the legs swelled, and he died on the 11th of March.

Post mortem Examination.—On raising the integuments, the lower portion of the pectoralis major (its fibres were thin and pale) was seen covering the upper half of the tumor, which, when fully exposed, was found to be closely adherent to the ribs. By dissecting it away from its attachment, a large opening was found (about three inches in diameter) through the fifth, sixth, and seventh ribs, into the chest; the bones at this part having become carious and broken down.

The tumor, when cut into, exuded spots of purulent matter in various parts, whilst the part contiguous to the opening of the chest was found to have small spiculæ of bone intermixed with it. On opening the chest, and raising the sternum and cartilages, a large white substance (six ounces by weight) was found occupying the anterior mediastinum; it had much the colour and consistence of cheese, and when cut in various parts gave vent to a purulent matter of a tolerably healthy appearance. A considerable quantity of serous and purulent effusion was found in the left side of the chest.

The left lung was completely broken down in texture; not a single particle of it could be found at all healthy; it instantly gave way to slight pressure between the thumb and finger; the whole of it had been greatly enlarged, which, together with the white sub-

stance, occupied more than one half of the chest, and thus, by its increase, pushed the heart to the opposite side.

The right lung was healthy, with the exception of three small prominences on its surface, which, when opened, gave issue to a purulent discharge.

The heart was found placed between the right lung and the tumor in the anterior mediastinum; it was small and flabby, but otherwise quite healthy.

Pericardium a little thickened.

Pleura costalis healthy, except near to the diseased parts of the ribs.

ON THE SIMILARITY OF VIEWS

ON

DISEASES OF FEMALES,

OF DR. MARSHALL HALL, AND DR.
ADDISON;

By *****.

—

WHEN different men take up the same investigation independently of each other, and come to the same or similar conclusions, it affords a strong presumption that they have alike arrived at the truth. This agreeable conviction flashed upon my mind, the other day, as I was reading the able and eloquent lecture of Dr. Addison on disorders of females arising from uterine irritation. How identical, said I, are these observations with those of Dr. Marshall Hall. I turned to Dr. Hall's volume, and I was more and more struck with the force of

truth as displayed by the similarity in the conclusions drawn by these authors from their distinct observations of the same objects.

The reader will partake of my feelings on casting his eye over the following parallelism of passages, extracted from the two works of these two writers. Indeed the only difference appears to be their views of the causes and effects in the series of the phenomena. But I will proceed to give the parallel, and subjoin any remarks I may have to make of my own; simply premising that Dr. Hall first traces the general symptoms, and counts the morbid affection of the bowels amongst the first, and that of the uterus amongst the subsequent links of the chain. Dr. Addison inverts this order: let the reader compare pages 15, 25, 51, 59, of the former author, with pages 10, 21. Having made this remark, our work will be much shortened.

Dr. Addison states:—

1. Of these painful affections, the most frequent are—1, pain situated under the left mamma, or under the margin of the ribs of the same side; 2, pain under the margin of the ribs of the right side; 3, 4, pain in the course of the descending, or of the ascending colon; 5, pain affecting the abdomen generally; 6, pain in the region of the stomach; 7, pain in the region of the kidney; sometimes extending down the course of the ureters to the bladder; (*abridged from page 21.*)

2. I have known patients literally blanched by repeated bleeding and cupping to remove the neuralgic pains.

3. I say nothing of blood-letting, as the propriety or impropriety of this must be apparent from the state of the circulation, always bearing in mind that such subjects bear bleeding badly, &c.
—Page 40.

Dr. Hall states:—

1. In the course of this disorder there is frequently pain, more or less severe, more or less continued; and in such different forms and situations as to resemble, in different cases, attacks of gall-stones, inflammation of the liver, spleen, kidney, or of the intestine, or peritoneum. There are sometimes symptoms of affection of the bladder. The pain of the side is peculiar, and too common to be a mere accidental complication.—Page 63.

2. The first case in which I saw the necessity and importance of these distinctions had been successively treated as inflammation of the brain, and inflammation of the liver, by bleeding, blisters, and leeches, to an almost incredible extent.

3. A source of distinction exists in the effects of remedies; early fainting from blood-letting is observed in the complications of disorder of the general health; inflammation on the other hand seems to protect the system from the effects of loss of blood, &c.

But it would take me too long to enter fully into a comparison of the opinions of these two authors. I would merely add that the list of remedies is very nearly the same.

In fact, the same cautions not to bleed indiscriminately and indiscreetly—not to esteem this *the* remedy, yet not to neglect it absolutely in every case, but rather to have recourse to aperients, to the class of anodynes, to counter-irritants, or to local applications of a soothing nature. These are the distinctions given alike by Dr. Addison and by Dr. Marshall Hall.

And now I am upon the subject, I would just mention that Dr. Abercrombie, and the lamented Dr. Gooch, have also recently been plainly led into a similar train of thought and of investigation. They who feel interested in the subject may turn to page 67 of the second edition of the work of the former of these authors on Diseases of the Brain, and to Dr. Gooch's work, page 144.

Indeed, after all that has been recently done in this matter, no one can doubt that there exists two classes of morbid affections: the first that of inflammation, the second that of irritations. Our language is still, indeed, too vague on these subjects. M. Broussais' irritation, for instance, is but a lower form of inflammation. May not the same be said of Dr. Gooch's irritable uterus? However this is confounding things that are different; local pains, not inflammatory, nor even sub-inflammatory, exist from intestinal, or uterine, or renal, or other irritation, not requiring, not bearing, blood-letting; but yielding, satisfactorily, to another class of remedies. Dr. Addison and Dr. Hall have at least established these points—points not less obvious, and far more important in practice, than the addition to our museums of mere scraps of morbid anatomy.

It now remains an admitted fact, then, that irritation and inflammation are alike real existences in nature: that we must bleed to cure the one, that we must not bleed to cure the other; that we, in a word, must apply a distinct class of remedies in these distinct cases of morbid affections.

ANALYSES & NOTICES OF BOOKS.

“ L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

Sketches of the Medical Topography of the Mediterranean; comprising an Account of Gibraltar, the Ionian Islands, and Malta: to which is prefixed, a Sketch of a Plan for Memoirs on Medical Topography. By JOHN HENNEN, M.D. F.R.S.E. Inspector of Military Hospitals, &c. Edited by his Son, J. HENNEN, M.D. Mem. Royal Med. Society, Edin. &c. 1830.

WHEN, a few weeks ago, we recommended Dr. Hennen's “Principles of Military Surgery” to our readers, we did not think we should so soon again have had occasion to notice another work by the same author. Dr. Hennen was a distinguished ornament of the department to which he belonged, and has done much by his writings to advance military medicine and surgery; while the example of his activity and zeal will prove a stimulus to the industry of those who come after him. Our professional brethren in the army have, far beyond civil practitioners, an opportunity of observing disease in a variety of climates, and modified by the differences which prevail in the habits of different nations. Too often these opportunities have been suffered to pass unimproved; but of late years these investigations have been much encouraged by Sir James McGrigor, to whom the medical officers of the army are in no small degree indebted for the high rank they hold in the professional community. Many of Dr. Hennen's remarks were originally contained in official reports made to the Director-General, and we observe that it is under his “encouragement and support” that the work now appears edited by the son of its deceased author.

The present volume is chiefly occupied by observations relative to the medical topography of the Mediterranean; those classic shores, where each rock has its name, and every rivulet has been the theme of poets. How mortifying the picture presented by the author before us of the altered condition of these countries!

The general plan adopted by Dr. Hennen, and recommended by him for

the conducting of similar investigations, is to treat, *first*, of the physical geography of the place to be described, with notices relative to its natural history; *secondly*, of the inhabitants, as to their food, manner of life, &c.; *thirdly*, of diseases, whether endemic, epidemic, or sporadic, affecting the human species, the lower animals, and plants; and *fourthly*, of various miscellaneous subjects not coming under the other heads. Under these different divisions we have a mass of well-arranged and accessible facts connected with the medical topography of Gibraltar, Corfu, Cephalonia, Zante, Santa Maura, Ithaca, and Malta. The first and last of these occupy the greatest share of attention, as the most important stations. In the account of Malta there is much very interesting information on the subject of the plague, which alone will render the volume one of frequent reference.

The nature of the work necessarily precludes the possibility of analysis, inasmuch as it consists of a collection of detached facts; but we shall occasionally avail ourselves of these, and lay some of them before our readers as opportunity serves. At present, we wish to direct the attention of all interested in the pursuits which are comprised under the title of "Medical Topography," to the great assistance which the labours of Dr. Hennen are calculated to afford them, and in an especial manner we would point it out to the medical officers of the army, as a work which none of them ought to be without.

MEDICAL GAZETTE.

Saturday, April 17, 1830.

"*Idcel omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.*"—CICERO.

ATTACKS ON DR. BURROWS.

'The "Times," a few days ago, in commenting on Dr. Burrows's letter to Sir Henry Halford, while it admitted that the Doctor had been "unfairly treated," and had satisfactorily disproved "the most material of the imputations cast on his character," added, nevertheless, that there was no combination

against him as he seemed to suppose; and, in fact, that he was not of sufficient importance to be the subject of a "conspiracy." Now in all this we quite agree with the "leading journal;" but although there may have been no conspiracy, there certainly has been a succession of unfounded attacks on that gentleman's character, — there has been a regular *set* made at his reputation by the public press.

John Bull is the creature of prejudice. An ignorant quack, who cannot write two sentences grammatically, and who is as innocent of medical knowledge as he is of witchcraft, is allowed to humbug the public, and the conductors of the press look quietly on and let it pass—because it is the fashion. Again, if a well-educated, experienced, and skilful practitioner, make but the smallest mistake—real or supposed—the public vie with each other in running him down—he forthwith becomes the object of general condemnation, and all vent their virtuous indignation against his supposed atrocities. Persons who never take the trouble to inquire into the facts, are yet content to express their opinions as confidently as if they were quite masters of the case: anonymous writers in the daily papers are suffered to become parties in the discussion, and then farewell to any thing like common sense; thenceforward it is all hue and cry and clamour, and the *mad doctor* is hunted down like a mad dog.

The public in general know very little about the powers which set in motion much of the machinery by which they are influenced: a police reporter, for instance (a person occupying one of the lowest in the many grades of the literary community), in order to render his contributions more piquant, throws a colouring over what he has occasion to record which, without an absolute perversion of truth, may

yet give a different aspect to the whole transaction; and from this source, insignificant as it intrinsically is, did much of the clamour against Dr. Burrows originate. We are not now going to discuss the question of Mr. Davies's sanity or insanity; but we are anxious to direct the attention of our readers to one of the consequences which has grown out of the late commission of lunacy, and although it refers more particularly to an individual, it cannot be uninteresting to the profession at large. No one can tell when his turn may come to be put to a similar trial; indeed, the more elevated the place any one holds, the more exposed he is to have his reputation tainted by the breath of calumny.

That Dr. Burrows was the object of *ex parte* statements in the newspapers, no one who reads his letter can doubt. Fortunate was the event for those opposed to him in the case of Mr. Davies, for he became a marked man, whom it was both safe and expedient to attack. The conduct of barristers on some occasions is very extraordinary: out of Court they are generally found to be liberal-minded and gentlemanly men, but the moment they put on their gown, these qualities seem to be laid aside. We could allow much to the zeal of pleading, and the excitement of rivalry; but there are some things which we cannot so easily reconcile to our notions of right and wrong. We should think, for instance, that a falsehood was no less a falsehood when uttered in gown and wig, than spoken in a man's ordinary costume; yet it is notorious that counsel positively assert, not only what they do not know to be true—but what they do know to be false. Thus in the case we are considering, various charges were advanced against Dr. Burrows, involving both his professional and moral character, which were utterly destitute of foundation; yet is not the counsel who made

them regarded as having exceeded his duty! There is another rather singular circumstance connected with this point: when evidence was offered to disprove these allegations, it was refused, as not consistent with the practice of the Court. Now to men not initiated into the mysteries of the law, it appears somewhat paradoxical that it should be according to rule to suffer statements to be made, and against rule to admit counter-statements. One would suppose that if an allegation were relevant, it would be deemed essential to ascertain whether it were true or false. While it is otherwise, well may the decisions of the law be proverbial for their uncertainty!

The leading counsel for Mr. Davies directed all the power of his eloquence and concentrated bitterness of his sarcasm against Dr. Burrows, and the press forthwith re-echoed the clamor.

But will it be credited that the Quarterly Review has joined in the common cry—that the Quarterly, which used to hold so high a rank in the periodical literature of the country, has descended from the dignity of the critic to the personality of the partizan—that it has endeavoured to connect the names of Burrows and Davies as those of the oppressor and the oppressed? The public mind, which is always roused into phrenzy when any one but hints at danger to the liberty of the subject, was beginning to recover its healthy tone, when, lo! the Quarterly comes out with a thundering article, in which the injustice and asperity of all who had preceded it are far outdone. A work of Dr. Burrows, long published, is placed at the head of a discussion on the case of Mr. Davies. Dr. Burrows, who did not sign the certificate of his insanity—who did not send him to Clapham—who, when there, used every effort to have him removed; Dr. Burrows, against whose humanity and skill there is not the sha-

dow of an imputation, is ironically depicted as his "gentle and judicious" physician, endeavouring to incarcerate him in a strait-waistcoat;—and worst of all, Dr. Burrows, who in this business has been more sinned against than sinning, is stigmatised as the inventor of a new crime, to which his name is to be attached like that of the notorious criminal Burke. "Let all the friends of the BURROWSED (says the Quarterly) remember this lesson." It is sufficient to point to these circumstances to rouse the indignation of our readers; it is unnecessary for us to enlarge upon their injustice and cruelty.

But we have another motive for alluding to this article, and another character to clear. It is generally attributed to the pen of a late distinguished physician. Some part of it is doubtless his—yet even that part was written on his death-bed, when his mind and body were alike weakened by disease; it displays not the terse vigour of his former essays. But there are portions of it which we are satisfied Dr. Gooch never penned;—such, for instance, is the above miserable attempt to coin a word, and for ever stamp with infamy the name of a humane and meritorious physician. We speak not unadvisedly when we assert, that the most objectionable passages in the Review were added after it had passed from Dr. Gooch's hands.

Of Dr. Burrows personally we know nothing. It is but lately that we criticized his opinions on some points, with regard to which we had the misfortune to differ with him, while then as now we entered upon the subject exclusively on public grounds. The members of our profession ought to make it common cause, and by their general support, prevent those injurious consequences which such a succession of attacks must otherwise be calculated to entail upon their object.

REMUNERATION OF GENERAL PRACTITIONERS.

THERE are some misapprehensions afloat on the state of the law as regards the remuneration of general practitioners. There is no legal enactment by which they are entitled to charge for attendance as well as medicine, nor did any such clause ever pass the House of Commons, as was erroneously stated in the *Lancet* last week. At present the only safe mode is for the practitioner to come to an understanding with his patient that he is to receive compensation for his attendance instead of his physic; and this, in the majority of cases, might be done without difficulty. The decision of Lord Tenterden, in the cause of *Handey versus Henson*, was evidently the result of that learned Judge's sense of what was right and fitting; but it neither has, nor can have, the authority of a legal enactment. To conceal this is quite absurd, for it is of the utmost importance for the general practitioner to know on what ground he really stands, and not to be misled into false security. That the clause alluded to never "passed the House of Commons," will appear by the following extracts.

From the Times of Tuesday, June 21, 1825.

"HOUSE OF COMMONS, JUNE 20.—The report of the Apothecaries' Bill was brought up, and a clause introduced by Mr. Hume, enabling apothecaries to charge for their attendance as well as for medicines only. That clause was agreed to without a division, and the bill was ordered to be read a third time on Thursday."

From the Times of June 25, 1825.

"HOUSE OF COMMONS, FRIDAY, JUNE 24, 1825.—On the motion of Mr. Brougham, the Apothecaries' Bill was read a third time, and passed; omitting a clause respecting a new mode of professional payment."

ROYAL INSTITUTION,

Friday, April 2, 1830.

WHITLOCK NICHOLL, M.D. VICE-PRESIDENT,
IN THE CHAIR.*Mr. Ainger on Radiation.*

NOTWITHSTANDING the doctrine of cold being a positive principle, which once very generally prevailed, has long become obsolete among philosophers, there are some phenomena attending radiation which have been thought to favour a belief in the existence of frigorific rays, and they have been alluded to lately, particularly in the *Encyclopædia Metropolitana*, as phenomena still unexplained, although, we believe, the rationale of the supposed paradox has been before the public for upwards of a quarter of a century.

To this circumstance Mr. Ainger directed the attention of the members, and illustrated his explication by a few experiments. It is somewhat difficult to isolate, and yet render intelligible, a fact so closely connected with the general principles of thermosophy, but we will endeavour to state the question briefly. All bodies, whatever be their temperatures, radiate heat, although in different proportions. A vessel of boiling water and one containing ice or snow both radiate heat, and though the one would seem hot and the other cold, as compared with the standard temperature of the human body, both would be cold as compared to molten gold—both would be hot contrasted with frozen mercury. All bodies likewise *reflect* heat, or at least a part of that which is radiated from other bodies, and impinges on them: those which reflect the most, radiate the least, and those which radiate the most, reflect the least, radiation and reflection being in an inverse ratio to each other; polished white metallic surfaces being the best reflectors and worst radiators, and rough black ones of paper, charcoal, &c. the best radiators and the worst reflectors; say in round numbers $\frac{1}{10}$ and $\frac{9}{10}$ to $\frac{9}{10}$ and $\frac{1}{10}$.

If a cool body, say a vessel one half blackened and one half bright, filled with ice or snow, be placed in a chamber, the thermometric temperature of which is 60° , very different phenomena result, if thermometers be placed at equal distances from it, according as

the surfaces are rough and black, or smooth and polished. Now as by the laws of radiation a rough black surface radiates about 9 times more freely than a smooth polished white one, the thermometer will receive from it 9 times as much radiant matter as from the other, and hence it has been argued, that it ought, when exposed to the rough black surface, to indicate a higher temperature, if heat only be radiated and not cold as well, than when exposed to the smooth polished side, which radiates only 1-10th as freely. The reverse, however, is found to be the fact, and this phenomenon has been supposed to favour the doctrine of the radiation of cold, or at least to be an opprobrium to modern thermology. But the argument is fallacious, and the explication very simple. All bodies radiate a part of the heat which they contain; at the same time reflecting one part, and absorbing another of that which they receive; and these processes continually going on, tend of necessity to equalize the temperatures of all bodies within the influence of each other, and to maintain them at a mean. Hence reflection, as well as radiation, becomes an important element in the account, and it was from the omission of this that the difficulty arose; for the polished surface, although it *radiate* only 1-10th so much heat as that which is rough and black, it reflects to the thermometer 9-10ths more of that heat which it receives from surrounding objects than does the rough and blackened side; and as the heat of the chamber is, by the statement, greater than that of the vessel, the phenomenon which does occur, and which has been esteemed a stumbling block, in fact should occur, when the calculations are correctly made. It is important that these explanations should be known, and we are glad to find them exciting the attention of philosophers.

Medal for Botanical Students, Zoological Specimens, &c.

In the library were several interesting zoological specimens, a queen white ant, scorpions from the Eastern Archipelago, &c. &c. a piece of wood and metal pierced by an insect; various models in costume of native Indians; and what we must not omit to notice, a very chaste and beautiful design for a medal proposed to be given to botanical students by the Apothecaries' Company.

Fatal Accident from Nitric Ether.

After the lecture, a gentleman communicated to us the following accident, which lately occurred at a druggist's, from a carboy of nitric ether being placed in a bed-room, and which bursting during the night, the chamber, the door of which was shut, and in which there was no chimney, became filled with the vapour, and the death of the servant, who was asleep, was the result. This is, at least, the second case of the kind which has come to our knowledge, and some discussion ensued as to whether death was occasioned by any directly deleterious quality of the vapour, or indirectly by the exclusion of atmospheric air; the latter, we should think, the more probable hypothesis.

The meetings were this evening adjourned till after Easter, and the continuation of the Phonical Experiments announced for April 23d.

EXTRACTS FROM JOURNALS,

Foreign and Domestic.

PHYSIOLOGICAL PHENOMENON PRODUCED BY ELECTRICITY.

THE following singular results are by Professor Marianini, of Venice. He has stated, in a memoir published some time since, that a difference existed in the contractions of a frog when the electricity acted immediately upon the muscles, and when it acted upon the nerves which presided over the muscular motions; the former were called *idiopathic convulsions*, and the latter *sympathic convulsions*. The difference consists in this, that the former contractions occur in whatever directions the current of electricity traverses the muscles, whilst the latter take place only when the current which traverses the nerves proceeds in the direction of their ramification.

From this it follows that, when a current traverses a limb in the direction of the nerves, the two shocks should occur together; but, when it proceeds in the contrary direction, only the idiopathic convulsion should be produced. In the first case, therefore, the contraction should be stronger than in the second.

If the right hand be in contact with

the positive pole of a voltaic battery, and the left hand equally in contact with the negative pole, a contraction is felt in both arms every time the circuit is completed, but stronger in the left arm than in the right. If the direction of the current be inverted, the right arm feels a more powerful convulsion than the left.

If a hand be in contact with the positive pole, and a foot in contact with the negative pole, the circuit will be in the direction of the nerves in the leg, but not in the arm; and the contraction is much stronger in the leg, where the two effects are simultaneous, than in the arm, where the idiopathic effect only is felt. The same effect takes place if the electricity is passed from the shoulder to the hand, from one foot to another, from the knee to the foot, &c. &c.

This striking difference varies in different persons, especially in those who are paralytic. The current, from eighty pairs of plates, being passed from the hand to the shoulder of a person struck with hemiplegia, the muscles of the arm were scarcely contracted at the same place, where the convulsion was very strong, when the current was passed from the shoulder to the hand.

Sometimes this difference existed only in one limb. A woman, who had lost the use of the lower limbs, in consequence of an inflammation of the spinal marrow, felt the left foot contract with most force when it touched the negative pole of the pile; the right foot contracted with equal force, whether it was in contact with the positive or negative pole. This effect appeared to be due to a loss of nervous sensibility in the right foot, so that they had become indifferent to the direction of the electric current.

If a finger be immersed, as far as the second joint, in water, connected with the positive pole of a battery containing twenty-five or thirty pairs of plates, and the circuit be completed by touching the negative pole with a metallic cylinder, held in the other hand wetted, a shock is felt in the finger, not extending beyond the second joint: if the direction of the current be reversed, the shock is felt in the third joint. Upon giving attention, it will be found that the first shock is more external, and accompanied by a distressing sensation; whilst the second shock is more deeply

felt, and is accompanied by no particular sensation at the place where the finger touches the water. The effects are accounted for by the supposition that, when the finger touches the negative pole, the simultaneous occurrence of the two convulsions causes the stronger contraction; and that, when the finger touches the positive pole, the electricity which traverses the nerves proceeds in a direction contrary to their ramification, and in place of producing a shock, occasions the peculiar sensation.

If two metallic cylinders be covered with wet cloth, and one being held in each hand, contact is then made with thirty or forty pairs of plates, moderately active, besides the shocks which are felt each time the communication is completed, there is a particular sensation in the palm of the hand, communicating with the positive pole. This sensation has been very distinct in some persons sensible to the effect of electricity; and they compared it to that pricking sensation often felt in the hands or feet when the nerves have been compressed for some time together.—*Quarterly Journ.—Bib. Univ.* xlii. 287.

became the particular substance. Corrosive sublimate, equivalent to 6 grains of peroxide, only remained undecomposed, and of course some peroxide remained diffused through the precipitate: this may be removed by boiling the whole with about 100 grains of muriatic acid diluted with water; the salt is then perfectly black, dense, crystalline, and frequently very brilliant.

Mr. Phillips calls this substance a dipermuriate of mercury; considering it not as a compound of oxide and chloride of mercury, with water of crystallization, but of muriatic acid and oxide of mercury. That it contains no water of crystallization is considered as proved, because, when the crystals are put into a glass tube, and the latter heated in a salt-water bath, no moisture rises from them, and the crystals undergo no change. At a higher temperature, water, corrosive sublimate, mercury, and calomel, are produced.

Considered as a dipermuriate of mercury, the composition of this substance is as follows:—

Muriatic acid.....	1 atom ...	37 or 7.8
Peroxide of mercury, 2 atoms ...	432 .	92.2

469 100.

Phil. Mag. N.S. vii. 129.

ON A NEW COMPOUND OF MERCURY.

By Mr. Phillips.

On adding carbonate of lime to a solution of corrosive sublimate, and heating the mixture, a dark-coloured precipitate was formed, crystalline, very heavy, and the larger crystals nearly black; very slightly soluble in boiling water, and scarcely at all in cold. It dissolved in acids, and gave peroxide of mercury by potash, and chloride of silver by nitrate of silver.

Upon trial it was found that no excess of carbonate of lime rendered the change of the corrosive sublimate complete, the muriate of lime formed at the same time producing a counteracting effect. When hard carbonate of lime, as calcareous spar, was put into the corrosive sublimate solution, months were required to obtain only a few crystals of salt. Powdered and precipitated carbonate of lime acted more readily.

The following process gave the new compound quite pure:—272 grains or 1 atom of corrosive sublimate was dissolved in water, and boiled with 648 grains or 3 atoms of peroxide of mercury; a dark precipitate soon began to form, and eventually nearly the whole

ALIMENTARY TUBERCLE OF VAN DIEMEN'S LAND.

A singular substance has been found at the depth of a foot or a foot and a half in the earth of that country. It has not yet been described, but is called *indigenous bread*. It is covered with a thin skin, has a rounded form, like a potatoe or yam, and is sometimes as large as a man's head. When cut, it appears as if composed of a solid spongy mass, containing a considerable quantity of alimentary matter. No root or fibre has been found adhering to it, so that sometimes it has been thought to be a sort of terrestrial polypus, possessing a principle of animal life. The only indication of its presence which the natives have, is the occurrence of an exceedingly small leaf, which rises from the earth, and is connected with it by very thin and delicate fibres, which break whenever the tubercle is raised.

—*Asiatic Journal*.

HOSPITAL REPORTS.

SMALL-POX HOSPITAL

To the Editor of the London Medical Gazette.

SIR,

A PERUSAL of the last report to parliament from the National Vaccine Establishment (see London Medical Gazette, No. 122, page 24) has induced me to think that a brief sketch of a series of cases in which small-pox has succeeded to vaccination, may not be without its use at the present moment. Such a detail I have the honour now to enclose. It comprises the history of every case admitted into the small-pox hospital after (presumed) vaccination between the 1st January and 1st April of the present year. They amount in number to twenty-five. Instead of describing them, however, in the order of their admission, I have thought it best to arrange them in the order of their severity, beginning with the mildest. My object being a faithful narration of facts, I shall refrain from all comment upon the cases, at least for the present.

I remain, Sir,

Your very obedient servant,

GEORGE GREGORY.

31, Weymouth Street, Portland Place,
April 9, 1830.

Cases of Small-Pox after presumed Vaccination.

CASE 1.—Sarah Grunstreet, æt. 16, was vaccinated at Ashford, in Kent, when young. Has upon the arm one excellent cicatrix. The small-pox proved of an exceedingly mild sort, maturing on the fifth day. These cases, which are usually called chicken-pox in the adult, I distinguish by the title *varicella variolodes*. This patient was admitted January 8th, 1830, being the third day of eruption. Discharged cured January 15th. Duration in hospital eight days.

CASE 2.—James Wright, æt. 20, was vaccinated at Rye, Sussex, twelve years ago. No perceptible cicatrix. *Varicella variolodes*. Admitted January 12. Discharged January 19th. Eight days in hospital.

CASE 3.—Mary Barker, æt. 16, vaccinated two years ago in the country. No perceptible cicatrix. *Varicella variolodes*. Admitted February 11. Discharged February 18th. Eight days in hospital.

CASE 4.—John Hubberfield, æt. 11, vaccinated at Bath when five years of age. One good cicatrix. This boy came from a house in Somers' Town, where small-pox was raging. The eruptive fever was very severe.

There were, however, not more than twelve minute pustules on the face, maturing on the fourth day*. Admitted March 4. Discharged March 16th.

CASE 5.—James Wiles, æt. 19, says he was vaccinated at the small-pox hospital when young. I did not succeed in tracing the name, but he has three good scars, arranged in the mode usually practised at the hospital at that period. *Varicella variolodes*. Admitted March 8th. Discharged March 16th.

CASE 6.—Charles White, æt. 21, vaccinated in Hampshire when young. Has one good cicatrix. *Varicella variolodes*, but with great general debility and irritable stomach. Admitted March 28. Discharged April 5. Still weak.

CASE 7.—John Town, æt. 23, vaccinated at Yatly, in Hampshire, when young. One small scar on the arm. Has small-pox, of the distinct sort, well characterized for the first five days, but subsiding rapidly. Admitted February 17. Discharged February 25. Duration in hospital nine days.

CASE 8. John Steel, æt. 20, reports that he was vaccinated at a village, near Ipswich, when young. No cicatrix is discernible upon the arm. Small-pox of the distinct sort, but modified. Admitted February 3. Discharged February 19. Seventeen days in hospital.

CASE 9.—Joseph Betts, æt. 20, vaccinated at Bungay, in Suffolk, when young. One good cicatrix is to be perceived. Small-pox distinct, but modified. Admitted January 5. Discharged Jan. 19. Fifteen days in hospital.

CASE 10.—William Barnham, æt. 19, vaccinated by Mr. Stow, at Buckingham, when an infant. One perfect cicatrix; small-pox, semiconfluent, threatening to be severe, but modified in its progress. Admitted March 31. Now (April 9) convalescent, and fit to be discharged.

CASE 11.—William Donaldson, æt. 22, vaccinated at Arbroath, in Scotland, when young. His arm shews one excellent cicatrix. Small-pox confluent, but modified. A severe attack of ophthalmia took place during the fever of maturation. Admitted March 23. Discharged cured April 5. Duration in hospital 14 days.

CASE 12.—James Cox, æt. 23, was vaccinated in Sussex when young. There is one good scar on the arm. Has small-pox, of the confluent kind, which, however, matured kindly. Admitted March 24. Is now (April 9th) convalescent, and fit to be discharged.

CASE 13.—E. S. æt. 18, vaccinated at East Grinstead, when a year and a half old,

* This is the case alluded to in the London Medical Gazette, vol. v. page 795. (Proceedings of Westminster Medical Society, Saturday, March 6.)

by Mr. Collins, surgeon. Two excellent scars are observable upon the arm. The vaccination in this boy was considered so fine that the children of — Esq. a magistrate of the county, were vaccinated from him*. Small-pox very confluent, and for several days threatening danger. No secondary fever, however, took place, and the convalescence was not interrupted by a single bad symptom. Admitted March 23. Is to be discharged this day (April 9th).

CASE 14.—Edward Shaw, æt. 15, reports that he was vaccinated in Hertfordshire when young. No cicatrix, however, can be detected. Small-pox, of the confluent kind, but maturing rapidly and kindly. Admitted January 8. Discharged January 22. Fifteen days in hospital.

CASE 15.—William Grieve, æt. 22, vaccinated in Edinburgh when young. One cicatrix on the arm, not indented deeply. Small-pox, with a copious semi-confluent eruption, running its ordinary course. Convalescence rapid. Admitted January 17. Discharged January 29. Duration in hospital 13 days.

CASE 16.—Louisa Crawley, aged 17, reports that she was vaccinated in this hospital when young. Is one of a family of sixteen, all of whom have been vaccinated here. I cannot find her name in the register book. Her arm exhibits three good cicatrices. Small-pox, of the confluent kind, maturing on the seventh day. Her constitution being weak, suffered severely under the attack. Convalescence very tedious. Admitted January 11. Discharged February 18. Duration in hospital nearly six weeks.

CASE 17.—Mary Ann Huson, ten years of age. This girl was vaccinated at a general parish vaccination when an infant, by — Esq. a surgeon at Hatfield. Two small papule appeared on the arm, which the mother felt assured would "never stand." No cicatrix remained. Small-pox of the semi-confluent kind, exceedingly severe, followed by tedious boils and abscesses, and great constitutional debility. Admitted January 22. Discharged February 26, still in a very weak state†. (Has since recovered perfectly).

CASE 18.—Mercey Bowen, æt. 23, vaccinated at a village near Ipswich, twenty years ago, by the regular doctor of the place, who told the family if ever she took small-pox afterwards "he would attend her for nothing." Has one good cicatrix. Small-pox of the semi-confluent kind, very severe at first but maturing kindly. Admitted January 26. Discharged February 16. Stay in hospital three weeks.

* These and other particulars were communicated in a letter from the young man's mother, received about ten days ago.

† In this case the vaccination was avowedly imperfect. The case is introduced here, however, to shew the necessity of careful superintendence on the part of country vaccinators.

CASE 19.—John Place, æt. 16, was vaccinated, when young, in London, but it is not known where or by whom. One good scar on the arm. Small-pox confluent, severe, unmodified, followed by great debility. Admitted February 13. Discharged (still weak) March 26.

CASE 20.—Charles Clow, æt. 15, has always been given to understand that he was vaccinated at Wickermarket when young. No cicatrix, however, is perceptible. Small-pox confluent and severe, but without secondary fever. Admitted February 17. Discharged cured March 16.

CASE 21.—Harriet Hyatt, æt. 21, was vaccinated in Sussex at seven years of age. Two superficial cicatrices are apparent. Small-pox of the distinct kind, but very much modified in its aspect. Ulcerated sore throat, with slight scarlet eruption upon the arms and breast came on a few days after admission, and proved extremely severe. Leeches to the throat, and purgatives, proved of no service. Under the use of decoctum cinchonæ, with aromatic confection, and a liberal allowance of brandy, she eventually recovered, but for several days she was in imminent danger. Admitted February 26. Discharged March 23.

CASE 22.—Francis Howland, æt. 26, was vaccinated at Sittingbourne, in Kent, when six weeks old. One scar is to be seen upon the arm. Small-pox confluent, laryngeal, unmodified, followed by extreme debility. Admitted February 26. Discharged quite well April 6.

CASE 23.—Elizabeth Skoltock, æt. 26, was vaccinated at twelve years of age in Shropshire. Remembers the circumstance perfectly. Says that the arm rose very well. There is one good cicatrix to be perceived. She caught small-pox by attending a servant in the same family having varicella variolodes, under the care of John Nussey, Esq. The disorder proved, in this case, confluent and severe, but without secondary fever. Admitted March 6. Discharged March 23.

CASE 24.—James Pratt, æt. 30, admitted January 14th. Reports, that in 1805 he was vaccinated at a parish vaccination in Suffolk, by a regular practitioner. Understands he had the measles at the same time. No cicatrix is perceptible. In all probability the vaccination failed. He had the confluent disease, of which he died January 21, the eighth day of eruption.

CASE 25.—Joseph Rayner, æt. 22, admitted January 17th. Was regularly vaccinated by Mr. —, when young, at Great Waltham, in Essex. His brothers, who came to see him during his illness, and whom I revaccinated, informed me that his arm inflamed greatly. No cicatrix is discernible, but this may arise from the copiousness of the eruption. The disease proved very severe, with laryngeal complication,

and he died January 22, the eighth day of eruption.

Besides the cases now detailed, the following eight reported their having been cut for the cow-pock at some former period, ineffectually: James Shillingford, John Palmer, Elizabeth Barnes, William Clelland, Thomas Taylor, Thomas Cass, Jacob Draper, James Drover.

Total of admission into the Small-pox Hospital between the 1st January and 1st April, 1830, 82, of whom died 19.

HOSPITAL SHIP GRAMPUS.

To the Editor of the London Medical Gazette.
SIR,

You will oblige me by inserting the accompanying case in an early number of the Medical Gazette.

I am, Sir,
Your most obedient servant,
J. Y. THORBURN.

Case of Priapism requiring Incisions.

Providence Smith, æt. 23, a tall and powerful Irishman, admitted under the care of Mr. Thorburn, Feb. 27th, about noon. Countenance indicative of extreme suffering from an erection of the penis, which is firmly and equally distended; free from heat or redness; pain most severe at the corona glandis; his urine scanty, and passes with great pain. Pains in the loins; pulse natural; tongue white, and complains of thirst; bowels constipated; restless at night.

Eighteen days ago considered himself troubled with worms, to remove which he eat at once nine heads of East Indian garlic. He became soon afterwards affected with febrile symptoms; and the same evening with an erection, which continued until 2 P.M. the next day. It returned every night, and subsided in the day until about eleven days ago, since which it has been permanent.

R Ol. Ricini, ʒj. Ol. Tereb. ʒss. fiat haust. stat. sum. Balneum Calidum. V. S. ad ʒxvj. R Opii. gr. ij. G. Camph. gr. x. fiat bolus.

In the evening—

Ol. Ricini, ʒij. cum. Ol. Croton, gtts. iv. at separate times. Eighteen leeches to the penis. Balm. Tepid. R Træ. Opii ʒj. Aquæ ʒvj. fiat fots constanter applicandus.

Feb. 28th.—Temporary relief from the leeches and the bath. In the course of the night dark clayey scybala evacuated with great pain. Blood taken yesterday chiefly serum, not buffed or cupped.

Hyd. Submur. ʒj.

4 P.M.—Left side of the penis was punctured, and temporary relaxation and abatement of pain followed,

R Hyd. Submur. gr. v. Pulv. Jalap. ʒj. fiat bolus statim sumendus et postea. Infusi. Sennæ, c. Sulph. Magn. ʒij.

9 P.M.—Bowels not moved. The relief from puncturing continued only for ten or twenty minutes; is now writhing with pain. Pulse weak; tongue furred. Refuses a repetition of the puncturing, or the administration of an enema.

R Ol. Ricini, ʒj. Ol. Tigllii. gtts. iv. statim.

March 1st.—Copious watery evacuation last night. Priapism continues. An incision made into the left corpus cavernosum, half an inch in length, through which flowed a considerable quantity of thick venous blood. A smaller incision was also made. The relaxation of the penis, and the relief from pain, was immediate; indeed the penis fell, as the patient emphatically describes it, with a "bob."

R Cal. gr. xx. Opii gr. iij. fiat bolus stat. sumendus. Cataplasin to penis.

2d.—No return of priapism; some swelling of the prepuce; mouth affected by the calomel.

5th.—Whole of the penis much swelled, but no pain or priapism.

Hirud. xij.—Lot. frigid.

March 9th.—Burrowing abscesses in corpora cavernosa, especially the left, in which it extends for two inches along the penis. Directory introduced, and a counter opening made with a bistoury, after which an injection of nitrate of silver (gr. v. ad ʒj.) was thrown in, and lint inserted.

14th.—Pressure applied to penis by means of adhesive plaister.

17th.—Penis free from swelling; no discharge from the openings.

19th.—Discharged at his own request; a slight induration of the left corpus cavernosum being the only vestige of the disease.

EDINBURGH ROYAL INFIRMARY.

Amputation below the Knee—Secondary Hæmorrhage—Ligature of the Femoral Artery.

NORMAN McLEAN, æt. 28, admitted under the care of Mr. Liston, Nov. 9th.

About four years ago sustained a severe sprain of the left ankle, which is of a livid color and much swollen, with several fistulous openings communicating with the joint. By the introduction of the probe, the bones are felt denuded, rough, and softened. The motion of the joint is very imperfect,

and attended with slight pain. Several small pieces of bone have at different periods been discharged. Pulse above 90, and of good strength; no diarrhœa, or night sweats; bowels regular; appetite good.

A variety of treatment had been pursued with the view of saving the limb, but the disease continued to advance, and, according to the patient's statement, his health has been considerably impaired. Had been in the hospital a twelvemonth previously, and then refused to submit to amputation.

11th.—To-day the limb was removed below the knee. The incision was commenced at the inner side of the tibia, and continued in a semilunar form to the outer part of the fibula; transfexion was then made, and a posterior muscular flap formed; the integuments on the fore part of the tibia were dissected upwards, so as to form a small anterior flap. The tibia was sawn through immediately below its anterior tubercle, and the head of the fibula was disarticulated. Three vessels, the popliteal and two gastrocnemial, were secured, and the flaps retained by stitches.

Mr. Liston stated that, in hospital practice, he prefers the amputation immediately below the knee to that at the middle of the leg; as, in the former case, the limb is of much greater use to the patient, he being able to follow his occupation with greater ease and security, and at less expense, by resting on the knee, than by using the artificial limb applied to the middle of the leg. He also prefers the amputation above described to the circular operation commonly practised at this point. In the former, much fewer vessels require to be secured, adhesion is in general more speedy, the end of the bone is better supported, and there is less chance of sloughing. He has lately made comparative trial of both operations in a considerable number of cases in the hospital.

The cartilages of the joint were almost entirely absorbed, and the denuded surfaces of the bones were in a carious condition. The bones of the tarsus were much softened and extensively ulcerated.

13th.—The stump has been dressed and looks well. Bowels rather constipated.

Habeat Pil. Colocynth. gr. ij. c. Pil. Hydrarg. gr. j. and an anodyne draught in the evening.

The patient seemed to be doing remarkably well till the morning of the 16th, when slight hæmorrhage occurred from the stump; cold applications were employed: the oozing, however, continued, and a considerable quantity of coagulated blood was removed from the wound, which was then stuffed with lint. In the evening, the hæmorrhage became more profuse, and the superficial femoral artery was secured by Mr. Liston, at the usual situation in the thigh. The bleed-

ing was immediately arrested. On removing the stitches, the flaps were found separated from each other by coagulated blood, and no adhesion had taken place.

18th.—Slept little during the night; pulse natural; bowels slow.

Habeat Ol. Ricini ʒj.

20th.—The process of granulation is advancing rapidly in the stump, which is almost universally adherent. The wound in the thigh looks well; pulse natural. Ordered wine and nourishing food.

29th.—The ligature which was placed on the femoral artery, has come away; stump healing rapidly; health much improved.

15th Dec.—The patient has been out of bed for several days.

He left the hospital soon after.

GUY'S HOSPITAL.

Case of Sloughing on Dorsum of Foot.

WILLIAM FAIRBROTHER, 37 years of age, was admitted under Mr. Key, 24th March, 1830, with a large sloughy ulcer on the dorsum of right foot, extending from the roots of the toes to about two inches or more above the outer ankle, and occupying nearly the whole breadth of the foot. He states that this slough commenced ten days ago, in a small dark-coloured vesicle, at the root of great toe. This burst, and has gone on increasing to its present extent. The history of his ailments are as follows:—

About seven months ago he had an attack in his chest, which was termed, by the medical man who attended him, spasm of the heart, and inflammation of the lungs. From this he partially recovered, after copious depletion, &c. in about two months, but has never been entirely restored to his former health. He went about his ordinary avocations till three months ago, when his feet began to swell, his breathing became short and difficult, he felt fatigued on the slightest exertion, and was not able to walk up stairs without labour; his extremities became cold and much weakened, and upon this swelled state of the feet supervened the slough which is the immediate subject of his admission. He has had more or less of cough during the last seven months, but has never spit blood. Has been subject to gout in his feet.

His employment formerly was that of private secretary to the late Mr. Sheridan, with whom, and subsequently with others, he has travelled a good deal; and lately (for the last three or four years) he has been clerk to a printer.

It appears that he has been a very irregularly living man; he has drank freely of spirits, and been much addicted to venereal

indulgences. Notwithstanding which, his health has been very good till this illness.

March 25th.—His present state is as follows. Sloughy pieces of cellular membrane, &c. are loosely hanging at various parts of the sore, close around which the limb is rather warm, but a little further off cold. Pulse extremely feeble and frequent; tongue fissured, and somewhat dry and red; surface of the body nearly cold generally. Cannot rise in bed without increased distress of breathing. Heart beats strongly, therein being at variance with the pulse. Carotid arteries are seen pulsating, and especially on the right side, where the superficial veins of the neck are swollen and turgid. Has a cough, with free expectoration of mucus, slightly tinged with blood. Voice is hollow. He is of a pale dingy complexion, and is much emaciated and enfeebled.

Ordered, Cataplasma Cerevisiæ pedi.

Infus. Rosæ C. p. r. n.

Extr. Hyoseyami, gr. v. o. n. et subinde.

27th.—Chest examined by means of the stethoscope, &c. It was pretty resonant throughout, except a little dulness over the right scapula, and over the region of the heart extensively. Breathing murmur was also evident every where, save at those parts. The heart's beat was very diffuse, extending over the greater part of left chest, and towards the sternum. No peculiar râle attended it, nor was there any tumult in its action. There was a lengthened contraction of the ventricle, followed by an ordinary auricular beat. His health is nearly the same. He gets no sleep at night, his appetite is very bad, and spirits much depressed. A considerable quantity of slough came away in the poultice. The sore looks flabby, and without granulations. It is not painful.

29th.—To-day his chest was again examined, and nearly the same results obtained. There is a good deal of crepitation in various parts of the lungs generally, chiefly on the middle and lower part of right lung. The pulse is very feeble. Pain in right side of chest severe, and increased on inspiration. Cannot sleep at all. Voice much weaker, and his general debility is many degrees worse.

Ordered, Vini Rubri, ℥viij. quotidie, and a Mutton Chop. — Emplas. Lyttæ Thoraci.

30th.—Cough is much worse, and a good deal of bloody mucus expectorated. Appears in great distress. Bowels are opened about twice daily; feels no appetite at all for food.

31st.—Cough still worse. Voice no stronger than a whisper. Articulates with much difficulty, being interrupted by cough and difficult breathing. The bloody mucus was increased by the very first glass of wine

taken, which has therefore been discontinued. Pulse very small, quick, and feeble. Tongue moister a little, but fissured laterally. Sore looks better. He slept for a short time last night, and in his own opinion he is in less pain than he was yesterday.

April 1st.—To-day each symptom, as above, is decidedly increased, and the expression of his countenance more worn. To-day Dr. Hodgkin detected the bruit de rapé on the contraction of the left ventricle, caused probably by clots fringing the valves, and therefore it may only be temporary. Dr. H. did not notice it on former examinations. There is also, on lower side of left lung, on laying the hand over the spot, a sort of emphysematous crepitation, the cause of which cannot readily be explained.

2d.—He says he feels better, but he certainly looks as if he were sinking. No pulse can be felt at the wrist. Action of the heart not tumultuous, but diffused. Cough is very distressing; he brings up abundance of mucus, strongly impregnated with blood.

He went on thus till night; became slightly delirious, muttered and rambled a good deal, then became quiet, and at eight o'clock the next morning (3d April) he died.

Post-mortem Inspection, 53 hours after death.—The body externally offered nothing particular.

Chest.—So soon as the sternum had been raised up, the pericardium was seen, nearly double its ordinary size, occupying a good portion of the left side, and extending across to the right. The side of the left lung was adherent, at the lower part, to the pleura of the ribs, by means of some strong, old, vascular adhesions, just over the place where crepitation had been felt by the hand on the 1st April. Within the lower part of this lung there were two or three portions in a state of apoplexy, gorged with blood, and easily broken down under the fingers. In the superior part were several spots of tubercular matter, contained in tough capsules, and with surrounding hardness of the lung.

On the pleura of right lung, and especially at the lower part, between the lung and diaphragm, were some patches of very recent lymph, indicative of pleuritis. At the upper part, as on the left side, were several tubercular bodies, with a puckering round some of them, as if they had been contracted cavities. There was not much fluid in either pleura.

The heart was enlarged to nearly twice its natural size, both in thickness of substance and capacity of cavities. On its exterior the coronary vessels were seen beautifully filled. Both the cardiac and reflected layers of the pericardium were rough, and had the scabrous feel of old inflammation. Strings of recent effusion, too, were seen ramifying with the coronary vessels.

The mitral and tricuspid valves were

sound. In the right auricle there was a large lump of adhesive matter, slightly adherent to the auricle. This mass had an external nearly membranous texture, and appeared a little vascular. It enclosed in its centre some coagulated blood. The aortic valves nearly sound. There was a very slight roughness at two of the corpora sesamoidea.

In the cavity of the pericardium there were about three ounces of fluid.

Abdomen.—Liver healthy. Spleen somewhat pale, and mottled within. Stomach contained about four ounces of coffee-coloured fluid; its inner coat was every where red and granular. Also, within the stomach, about the centre of the smaller curvature, there was an ulcer as large as a shilling, irregular in shape; its edges and base were hard and well defined; its surface excavated and covered with a scrofulous-looking matter, such as is met with in ordinary scrofulous sores. [N.B. The patient never had vomiting or any other symptom which called attention to the stomach peculiarly.] The small intestines were turgid with blood, and the veins on the mesentery leading from them were full.

Kidneys small, irregular, rough, and contracted, and very much mottled. It had not been ascertained whether the urine was coagulable.

[The following interesting case, with the post-mortem examination, is taken from the clinical case-book: the patient was under the care of Dr. Bright.]

Tubercles in the Brain.

Amelia Humphreys, æt. 11, a delicate but healthy child, until five months ago, when she had a fit at school, from which she has never completely recovered. (The probable cause of the fit, and the particulars attending it, cannot be ascertained, either from the child herself or her friends.) She was leeches, blistered in the head, and had so far got the better of the attack that on coming home a month after she was able to walk with but little assistance. She relapsed, however, in a fortnight, and fell into the same helpless state in which she is at present.

Nov. 4th.—She has lost all power of moving the left leg, which is stiff, cold, and shrunken, the foot being drawn inwards. The right leg is similarly affected, but in a less degree; they are sensible to touch, and she cries when they are pinched. She still retains the use of the upper extremities, but in an imperfect degree; there is spasmodic action of the right arm occasionally, with shaking and trembling; the urine and feces are passed involuntarily; the aspect indicates much suffering and cerebral irritation. She complains of pain in her head, and screams violently; is fretful, restless, and

irritable. The pupils are dilated; the veins of head prominent; the cheeks flushed; pulse rapid, with slight cough and acceleration of breathing. She has not been drowsy nor delirious during her illness, nor her intellects in any way disordered. Two of same family have died of hydrocephalus.

Abrad. Capillitium. Embroc. comm. capiti raso diligenter appl.

Pil. Galb. C. et pil. Alces c. Myrrha, a.a. gr. v. o.n.

5th.—Fiat setaceum nuchæ. P.

7th.—Dry hacking cough, preventing sleep; feces passed in bed; less dilatation of pupils, and no pain in head.

M. Mucilag. ʒiv. Vin. Ipecac. ʒij. Syrup.

Simp. ʒss. ft. linctus, p. r. n. P.

(The mother stated to-day that a fortnight before her illness the child had been observed by her playmates to be dull and heavy).

8th.—Rambled during the night, and does not appear so sensible when spoken to. This morning complains at one time of her head, at another of her foot, as being the seat of pain. Cough troublesome, liquid and frequent dejections passed involuntarily. Pulse 140, and small; appetite voracious.

Hydr. c. cretæ, gr. ij. bis die. Inf. Cascarrill. c. Soda, t. d.

9th.—More restless and fretful during the night; screaming out, and referring pain to head. Otherwise the same. Pulse 160 P.

10th.—Cough unabated; thirst considerable; pupils of natural size; stools, of proper colour and consistence, passed in bed, as well as urine: in other respects the same.

11th.—The belly exceedingly swollen last night; the breathing shorter and more laborious, effected principally by action of diaphragm; hiccups came on early in the morning, and has since subsided; the respiration and pulse now more rapid; they are this morning 40 and 160 respectively. The irritable habit and fretfulness are subsided, and there has supervened more or less of oppression; (not coma or delirium). The appetite, which was great, is almost gone; the countenance pale; but cheeks are suffused from time to time with a purple flush. The abdomen is rather tumid; the feces always passed involuntarily.

The right arm is motionless, and firmly contracted, stiff and inflexible; the eyes directed to the left; and she never moves them, either when spoken to, or when requested. There was observed after taking nourishment this day a violent spasmodic action of the muscles of the left side of the face.

9 o'clock P.M.—Comatose and insensible; the eye-balls, which were set before, are now rolling continually; the mouth is drawn to the left side, not permanently but spasmodi-

cally; with shivering of mouth, which is firmly closed. Pulse 176, rapid, but not fluttering or faltering. The extremities and head warm; hiccuph renewed occasionally; abdomen more tumid; quivering and twitching of muscles of extremities; has taken nothing since 5 o'clock.

12th.—Dissolution imminent; the breathing sonorous, with mucous tracheal rattle; eyes dim and set; pupils contracted; pulse flags during inspiration, and then beats three or four hurried strokes during expiration. Forehead and extremities very warm.

Hirud. vj. temp.

Expired at half-past 4 in the afternoon.

Examination after Death.—The body was rather emaciated, and generally pale; nothing requiring notice was observed either externally to the cranium or between it and the dura mater. On raising the dura mater, a partial but close adhesion was observed between the two opposed surfaces of the arachnoid over the superior part of the middle lobe, about an inch to the left of the longitudinal sinus. The arachnoid was elsewhere naturally thin and transparent, and the pia mater was generally little injected. Beneath these membranes, and directly seen through them, there was an appearance resembling scattered collections of yellow pus, having in most instances a nearly circular figure, not exceeding a third of an inch in diameter; one or two of these patches were of a more irregular figure. On examination, they proved to consist, not of pus, but of tuberculous matter, imbedded in the cortical part of the brain. Sections of the brain exhibited similar tubercles in the corticle substance in other parts of the brain, as in the depressions between the convolutions. They were particularly numerous, although of small size, in that part of the hemispheres which is in contact with the falx, behind the corpus callosum. The adhesions of the arachnoid corresponded with one of these tubercles above-mentioned. On the under surface of the brain, three of these tubercles were observed on the right anterior lobe, and two on the posterior. On the left side, was one on the anterior part of the middle lobe, not far from the tractus opticus. There were three or four on the upper and under surfaces of the cerebellum; and there were several in the cineritious matter of the arbor vitæ, not visible externally; and one of large size in the corpus rhomboideum. There was likewise one in the cineritious matter within the corpus olivare. The medullary substance appeared to be universally exempt from such deposits, except that one, about the size of a hemp-seed, in the left hemisphere, near the corpus striatum, and so situated that it could not be decided to what substance it belonged. There was increased

vascularity, to a limited extent, around all of these tubercles; none of them were in a state of softening. The medullary substance in the posterior part of the left middle lobe, was somewhat softened; that of the posterior lobe on the right side less so. In the anterior lobe it was slightly and partially indurated. The medulla spinalis was minutely inspected, but offered nothing preternatural, either in the colour or consistence of either cineritious or medullary matter. The membranes were likewise healthy; but it would seem that the arachnoid and pia mater very tightly embraced the medulla, for when slight incisions were made through them, just sufficiently to wound the medulla, a portion of this protruded, so as to occasion a considerable elevation.

Chest.—The opposed surfaces of the right pleura were firmly adherent, by means of a vascular cellular membrane, which did not appear to be of recent formation. On the left side, the pleuritic adhesions were few and partial. Both lungs were thickly sprinkled with miliary tubercles, in which opacity had commenced; they were most numerous in the upper lobes.

Abdomen.—The most remarkable morbid appearances were the very general peritoneal adhesions, in the form of membranes and bridles. There were also a few adhesions between the diaphragm and liver. The omentum was not drawn up and corrugated, but remained spread over the intestines and adhering to them, and more slightly to the parietes. Many of the abdominal viscera, and especially the intestines, were thickly sprinkled with miliary tubercles, which were situated in the false membranes as well as under the peritoneum. Many of these tubercles were surrounded by a dark deposit in the adjoining structure. The liver was healthy and free from tubercles, but pale. There were a few small tubercles in the spleen, which was of moderate size, and rather firm.

BOOKS RECEIVED FOR REVIEW.

The Nervous System of the Human Body, embracing the Papers delivered to the Royal Society on the subject of the Nerves. By Charles Bell, F.R.S.

An Introductory Lecture to the Theory and Practice of Midwifery; being an Historical Account of that subject. By Thomas Greening, M.D. late Physician to the City of London Lying-In Charity, &c.

NOTICES.

“An Inquirer.”—We are not able to give the information; probably it might be obtained at Apothecaries’ Hall.

“Quæsitur.”—The new Pharmacopœia is not expected to be ready for a year to come.

LECTURES ON SURGERY,

Delivered at St. Bartholomew's Hospital,

BY WILLIAM LAWRENCE, F.R.S.

—, 1830, 3.

LECTURE XXXII.

CELLULAR SYSTEM—(*Continued.*)

Emphysema—Tumors—Sarcoma, Adipose, Pancreatic, Cystic, Mammary, Tuberculated.

EMPHYSEMA, gentlemen, is a Greek word, which means *inflation*, or *blowing up*; and in its medical technical sense it denotes the presence of air in the cellular texture of the body. Air may gain admission into the cellular texture in consequence of a wound in the lungs; generally from such a wound as is produced by the fracture of the ribs, or in consequence of a breach of surface of the lungs, produced by the bursting of an abscess. It has been said sometimes to arise in consequence of the efforts made by a female in parturition, and that it has happened from the reduction of a luxation of the arm, of old standing. In some rare instances emphysema has occurred spontaneously—that is, from some internal unknown cause; and we find it taking place in consequence of the decomposition of the textures of the body which occurs in mortification. The mere presence of air in the cellular texture of the body need not give you any anxiety; but the causes that give rise to its admission may be more or less important. The swelling that is produced by the presence of air is a soft tumefaction; the air gives way under the pressure of the finger, and escapes into the contiguous cells, the displacement of the air being attended with a peculiar sense of crackling. If the distention proceeded to so considerable a degree as to become troublesome on that account, all that will be necessary for you to do is to make a small puncture with a lancet through the skin, so

as to let out the air. When, however, the cause which produces the introduction of air into the cellular texture is at an end, the air that has been already introduced gradually disperses—probably it is absorbed, and no more inconvenience is experienced.

Tumors.

The cellular texture of the body is frequently the seat of new productions—that is, of the deposition of new matter, forming an enlargement of the part in which it takes place; or, in technical language, constituting *Tumors*. Now, as the word tumor merely means swelling, all kinds of enlargement come under the term, etymologically considered. Thus various states of the different organs of the body, very dissimilar from each other, are attended with enlargement, or swelling; and therefore, so far, have a claim to be considered under the head of tumor. The word tumor, in fact, merely denotes the circumstance of enlargement, or external projection; and were we to arrange diseases according to circumstances of this kind, which do not arise out of the essential nature of the affection, we should bring together a very heterogeneous assemblage of affections, not allied to each other in any respect, except this single point of producing enlargement in bulk. I have already had occasion to mention what a strange collection of diseases is found under the head *tumores* of Cullen; and in the *Treatise on Surgical Diseases*, by Baron Boyer, you will find an equally ill sorted assemblage. Under the head of tumors he treats of erysipelas, phlegmon, boil, carbuncle; of malignant pustules, of aneurisms, or those tumors produced by the dilatation of blood vessels, aneurism by anastomosis, and so forth; of schiirrus, of cancer, and of œdema.

Mr. Abernethy wrote an essay on the classification of tumors, in which he very judiciously proposed to characterise and distinguish them, according to the differences of their anatomical structure; and he likewise proposed to restrict the term tumor to those

swellings which consist of a new production, which constituted no part of the original composition of the body. Thus we exclude from our idea of the word tumor, simple enlargement of parts, dilatation of tubular and hollow parts in consequence of the fluids which they naturally contain, the displacement of parts, such as in hernia, where an organ belonging to one situation is preternaturally thrust into another:—all these are got rid of, and we restrict the term to a very different class of affections—those enlargements of a part in which there are new productions that did not constitute any part of the original composition of the body.

Now, definition is not a very easy thing; and with respect to the one that I have just quoted to you, we must observe that it wants a little amendment, because as it now stands it includes the enlargement of the uterus in a state of pregnancy. When the uterus becomes impregnated, there is a new production, which did not constitute an original part of the body. Thus the impregnated uterus literally comes under Mr. Abernethy's definition of a tumor, though he did not mean that it should. It will be necessary, therefore, to modify this definition, so as to make it include simply those new productions which are deposited in the interior, or in the texture of any organ: then we escape these objections. Now unfortunately, in the very same paragraph in which Mr. Abernethy, in his Essay on Tumors, gives this definition, which I think useful as restricting the word tumor to a definite class of affections, he extends it so as to include others of a very dissimilar nature—that is, he includes under it the enlargement of parts, such as the glands—enlargements which are produced by the development of something in the texture of the part, and also those enlargements in which the original structure of the gland is entirely removed, and another substituted instead—that is, enlargement of the glands from a change of structure of the part. Now these are two distinct kinds of affection, and they cannot be made the subject of any common observation as to their origin, their increase, or their mode of treatment, and therefore I think they ought to be kept carefully distinct from each other.

It is true that some new productions may take place, such as either in the cellular texture of the body generally, or as depositions into the texture of the glands and other parts. This is the case at all events with fungus hæmatodes, and perhaps with carcinoma; and with respect to the former (that is, fungus hæmatodes), we find that when it is seated in a gland sometimes it occurs as a distinct deposition, we might say foreign to the proper substance of the gland—that is, completely defined and restricted within one certain part, and not disseminated

through the natural texture of the gland. In other instances we find that a general change takes place in the substance of the gland, by which the natural seems to be gradually converted into the fungoid structure. In these respects the two classes of affection approximate towards each other. We find that one of the same diseased formations may occur either in the cellular texture of one part of the body as a tumor, or an entirely new production; or it may take place as a similar entirely new production in any gland; or it may appear as a gradual conversion of the structure of the gland into its own peculiar character. Thus, as you see in other cases, we do not find marked lines of distinction between the various changes that take place in the body; but we find a gradual transition from the one to the other, with no very obvious or marked boundaries between them. I still think we ought to keep in mind the distinction between this new production or deposit into the cellular texture of the body, and those alterations of structure which occur in the various glands, by which the substance of the gland is gradually converted into a new kind of texture. With respect to the former—that is, the new production into the cellular texture of the body, which constitutes tumors—we may say generally, that we are incapable of acting on, or removing them, by any general or local measures whatever: with respect to enlargements or alterations of structure, attended with tumefaction of the glands, we generally combat them with more or less success by various measures.

Our next point of inquiry, then, is into the origin and modes of increase of the new or accidental productions. You will find three kinds of explanation given of the mode in which tumors are originally formed. In the *first* place, it is stated that blood is shed into a part—that it coagulates—that vessels shoot into the coagulum of blood, and organise it; and that the coagulum when thus organized may assume subsequently various kinds of structure, according to circumstances, of which we are ignorant. *Secondly*, It is said that coagulable lymph is deposited in the part—that vessels shoot into it; and that thus it becomes a new production, capable of assuming various characters of structure. *Thirdly*, It is said that tumors owe their origin to chronic inflammation, and they are enumerated as one of the results of that action. Now, although these three explanations are essentially different from each other, and therefore inconsistent, I think you will find in the essay of Mr. Abernethy, that in various parts he adopts each of them. We generally find when various modes of explaining any phenomenon of the body exist, that in point of fact we do not really know how it takes place; because, if we knew the precise way in which

the thing was accomplished, we should find that it took place in one mode, and that we did not want various ways of explaining it. Three explanations of the formation of tumors are more than enough; we only want to get at one. Now, in reference to the three modes of explanation that I have just mentioned, I can only state that my own opinion is, that tumors are not formed in any of these ways.

In the first place, we do not find that the formation of tumors is preceded by the effusion of blood into the part; we see nothing like that in investigating their history. On the other hand, we see that when effusion of blood takes place into the texture of a part, ecchymosis follows, either in a diffused form in the cellular texture, or by a collection of blood in one particular part, and that no tumor is the consequence of such occurrence. The blood thus effused is absorbed and removed from the part, and we do not see that tumors take place in consequence of it. In the same way effusion of coagulated lymph is occasionally occurring in consequence of inflammation, and the effusion is absorbed when the inflammation subsides; but the lymph is not organized and formed into a tumor—nothing of that sort takes place. If, by chronic inflammation, we mean that state of a part in which there is a recognisable degree of redness, heat, and swelling, we certainly observe no such phenomena preceding the development of tumors. Tumors take place insensibly; they often arrive at a considerable size before persons are aware of their existence, so that we see none of those phenomena preceding their formation which belong to our idea of chronic inflammation; in fact, if either of these explanations were correct, we should find that tumors would go through a certain stage; that in their early condition they would be seen in one stage of development, and that this development would be gradually unfolded, so that they would assume a different character according to their age; but we see nothing like this. On the contrary, if it be a fatty tumor, though it may not be larger than the end of the finger, it possesses all the characters of fat just as perfectly developed as if it were an enormous lump; and so we may say of every other kind of tumor. You do not observe them going through different stages; you do not see them existing as coagulated blood, or coagulable lymph, and then gradually assuming the appearance of a tumor of any kind; but from the first moment you recognise them, they are as perfect, though small in size, as at any subsequent period. I believe then, at last, that surgeons must be compelled to say, as the unlearned do, that tumors come of themselves—that is, the causes and mode of their original production

are really unknown; we cannot tell how they occur.

When the tumor is produced, we find that it derives its supply of blood from the vessels belonging to the part in which it has occurred; and we find that the vessels enter into it at various points of its surface. Tumors, however, have a natural tendency to advance towards the surface of the parts in which they take place; they arise towards the skin—they spread in that direction; and thus we find that the largest and most numerous blood vessels are found coming into the tumor at its base. Sometimes there is one considerable vessel, but generally there are a number of vessels entering into the tumor. The tumor gradually increases in the part; it condenses the cellular membrane, and forms it into a kind of capsule, an adventitious covering which surrounds the external surface of the tumor, and marks the boundary between that and the natural texture of the part.

When a tumor is produced, its increase no doubt takes place by the same process of nutrition which produces the regular enlargement of the various organs of the body. This process of nutrition in general, however, is more active in a tumor than in the natural texture that surrounds it. Thus you find tumors increase to a considerable size, often attaining a very great magnitude. This increase, however, is not constant; frequently tumors remain for a long time stationary—they neither increase nor diminish; at other times they grow very rapidly. In the case of some tumors there is a regular increase of size, and there seems to be hardly any limit to the magnitude which they may acquire; no other limit, in fact, except the degree of extension which the skin and the other surrounding soft parts will admit of. In other instances, having attained a certain size, the new production goes into other changes; it causes ulceration, the formation of fungus, sloughing, and so forth. This is the case with those productions which constitute malignant tumors, such as carcinoma, fungus, hæmatodes, and the like.

Those tumors which are more or less of a soft feel and consistence—those which may be called by the general or familiar appellation of fleshy tumors—have been designated by the technical name *Sarcoma*. *Sarcoma*, therefore, may be deemed equivalent to fleshy tumor—a tumor which is not bony, which is not cartilaginous—one which is not hard.—The first species of tumor which Mr. Abernethy describes, he calls the common vascular or organized sarcoma; and he mentions it as if it were produced by the effusion of coagulable lymph into the texture of the part, and by the subsequent penetration of vessels into the lymph, so as to render it organized. He says that when it has acquired

a certain bulk, the surface will be apt to ulcerate, and the tumor may slough out; and he gives one case that terminated in this way. I cannot say that I am acquainted with any other case of that description. I never saw effusion of lymph into a part organize in this manner. The singular case that Mr. Abernethy mentions seems to have been an accidental tumor; and he does not appear to have met with many instances of it, perhaps hardly enough to found a description of a regular kind of tumor upon it.

I may observe to you generally, that unnatural growths, which constitute tumors, will very frequently correspond in their structure to the parts in which they are produced. Thus, when a tumor is formed in the subcutaneous adipose tissue of the body, it is a mass of fat; when a tumor is observed in that kind of cellular texture which does not contain fat, it is of a cellular structure without fat. Tumors which are formed on the mucous membrane of the various parts of the body, have a mucous surface, and the part precisely corresponds to the mucous texture, such as polypi of the nose. Tumors formed on the cartilaginous ends of bones are cartilaginous; they constitute subsequently the loose cartilages sometimes met with in the joints. Thus we find generally that there is an accordance in the nature of its texture between the new production and the tissue which gives birth to it. This, however, is not essentially the case, because we may have the structure of carcinoma, or fungus hæmatodes, formed in the ordinary adipose and cellular tissues of the body.

Now, we have a kind of ordinary cellular tumor—that is, a tumor developed in the cellular texture where fat is not present; and these tumors grow to a very considerable size, without possessing any thing peculiar in their nature. I shall mention some examples of these tumors.

A very handsome finely-formed woman came to consult me. She looked remarkably healthy, but said she wanted my opinion about a swelling, and that she believed it was a rupture. She did not give me a clear account of it, and I said it was necessary for me to examine it. She consented, and then she turned aside one way and I turned the other, that she might have an opportunity of arranging matters with decency. I thought she was very long in getting this tumor undone, but at last the job was effected. When I turned to look, I expected to see a hernia, or a tumor, about the situation of the groin, perhaps the size of a walnut, or of an egg; but to my utter astonishment I saw, hanging from one of her buttocks, a mass about double the size of my head. I had a drawing made of it [which was here handed round the theatre, and contained a posterior and lateral

view of it]. The tumor was greater in breadth than the transverse measurement of the two buttocks, which, in a well-made woman like this, were not very narrow. When I came to inquire into its history, the lady told me that it had existed for four years; that it had not grown much during the two first years; that it had given her no pain, and that even in its present magnitude it produced no great inconvenience, except what was inseparable from its weight and bulk; but it interfered with no function, and did not even impair any. It seemed that it had commenced at the posterior extremity of the left labium, and had extended gradually towards the buttock, behind the os coccygis. It had a soft feel, and an obscurely lobulated surface. The integuments did not adhere to it, but were quite loose, so that they could be pinched up. The base of the tumor, especially towards the anterior part, was of uncertain extent—that is, I could not tell how far it went inwards beyond the labia pudendi, or towards the cavity of the peritoneum. She said her medical attendant had thought it was a rupture; and this led me to examine whether it was so. I tried to ascertain whether there was any motion communicated to it on coughing, but I could not see whether there was or not. I could not trace satisfactorily the tumor to its base; and I felt rather in doubt respecting its nature, and what ought to be done. I should say that it measured 32 inches in its greatest circumference, and 21 inches at its base. I recommended this lady to call on Mr. Wardrop, and ask his opinion. When we came to converse about it, he said that he thought it might be safely removed, and that this ought to be done. After considering all points in the case, seeing that her health was entire, that no function was affected, and that we could not trace any connexion that it had with any internal part, I determined on removing it. I performed the operation as quickly as I possibly could. There was of course a vast number of vessels bleeding very copiously. I did not stop to tie these, but allowed them to bleed; and by the time I had detached it the lady had lost a large quantity of blood, and was very faint. The tumor was only loosely connected to the glutei muscles, and to those parts to which it had recently extended; but there was a prolongation extending up the labium, toward the vagina. After tracing it upward, I thought it might be a thickening occasioned by the dragging of the tumor, and I cut it through and detached it. I brought the integuments together by eight sutures, and in less than a fortnight she was well enough to go back to the country, the parts being healed. She continued well, and not very long after the complete healing of the wound, she married. She returned to me again in about a year and

a half, in the last stage of pregnancy, and with a considerable reproduction of the tumor. It had acquired about one-third of its original magnitude. I told her she must come to me again after her delivery, which she accordingly did. I then found the tumor so large as to require a second removal, which I accomplished for her about a year and a half ago. On this occasion I traced the tumor very carefully up the labium, in the situation where I had cut it off, and I found a kind of neck ascending into the vagina, which I followed up to the symphysis pubis; and by dragging and drawing the part from that situation, it gave way, and came out pretty entire; so that it seemed to have its origin in that part. The wound speedily healed, and in eight days she was able to go back to the country, and has continued well to the present time. On coming to examine the tumor, and on cutting through it, I could not compare it to any thing except rather a condensed cellular tissue, free from fat, the interstices of which contained a serous or half gelatinous fluid, so that when it was left through the night in a dish, a large quantity of the fluid had gradually exuded from it, and it seemed to be simply that kind of condensed cellular tissue which might be expected to be formed in the tissue which belongs to the labia and the adjacent parts.

There are tumors occurring in the scrotum which proceed to an immense magnitude, distending the scrotum to an enormous size, and involving the integuments of the penis, ending at last in the production of a growth truly monstrous—in the formation of large tumors, that sometimes descend nearly to the ground, and out of one part or other of which the urine flows in an aperture like a navel. These occur principally in hot climates; the East and West Indies, for example; and the growths which are thus produced may amount to sixty or seventy pounds weight, or even still more. I have had no opportunity of examining any of these productions, but I rather think, from the accounts that have been given, that these are tumors of the cellular kind that I have just alluded to.

In the sixth volume of the Medico-Chirurgical Transactions there is an account of a tumor in a negro, which was removed by Dr. Titley; the mass weighed seventy pounds, and the patient did perfectly well. This leads me to say, that enormous as these growths are, and formidable as they appear, they may be very safely removed. Larrey, in his account of his campaigns, mentions having seen several cases of this kind in Egypt. He says that some of the tumors that he saw weighed sixty or seventy pounds; he mentions one in particular that was estimated to weigh one hundred and twenty pounds.

Now the production of these tumors is not simply confined to these hot climates, for we

find that they sometimes take place in our own country. Mr. Liston, in the nineteenth volume of the transactions of the Edinburgh Medical and Chirurgical Society, mentions the case of a youth, about twenty-two years old, who had a tumor, which had existed about ten years. There is a representation of it; and it seems almost doubtful whether the tumor or the body of the individual is the larger. Mr. Liston removed the tumor; and he mentions that the weight of it was forty-four pounds and a half after a good deal of blood and serous fluid had exuded from it. There is a similar case in the second volume of the "Transactions of a society for promoting medical and surgical knowledge," of a Hindoo, with a figure representing the growth.

When these tumors form in the adipose textures of the body, their composition is fatty, and it constitutes what Mr. Abernethy calls *adipose sarcoma: adeps* is the Latin for fat, and merely means fatty tumor. They are called by the French *tumeurs graisseux*. These consist simply of a mass of fat, and are hardly distinguishable from the ordinary fat of the body. They consist of a soft inelastic swelling, unattended with pain, giving no inconvenience unless from their bulk. We generally find that the bases of these tumors are lobulated. You here see an instance, [presenting a preparation]. This is a mass of fat that has been removed, and shews the appearance of the base of the tumor. They form very slowly, and the patients generally are hardly aware of their existence till they have attained some magnitude. The surface is surrounded by a thin white capsule,—the vessels which they receive are not large; they adhere but slightly to the capsule that contains them; so that when you have divided the integument and capsule you can easily turn them out—almost with the finger alone.

Excision is, in fact, the only remedy for one of these fatty tumors. As they are perfectly free from pain, as they give no kind of inconvenience except from their size, when the parts in which they form do not appear externally, patients do not complain till they have attained considerable magnitude. If they become troublesome from their size, we have nothing to do but divide the integuments, lay bare the surface of the tumor, cut through the capsule, and, as I have said, you easily turn the tumor out. If the tumor be so situated as to be subjected to friction from the dress, or irritation from any other external causes, you may find the integument and capsule adhering to it more firmly than you expect; and, under such circumstances, you find that at the lower surface it adheres closely to the parts on which it lies, and that numerous vessels enter it. I lately removed a pretty large mass of this kind from the back of the neck of a baker. The integu-

ments adhered very firmly; and the tumor was strongly attached to the muscles of the neck, and there was free bleeding. When the tumor was removed, I took up no less than twenty arteries, though I have observed that in general the arteries are few and small in fatty tumors. Now as we have seen that these tumors are of indolent character, and give no inconvenience to the patient, it frequently happens that they are allowed thus to increase to a very great bulk, and these fatty tumors constitute some of the largest specimens of such preternatural productions that we are acquainted with. Mr. Copeland removed a fatty tumor from a lady's thigh, which weighed twenty-two pounds. That is a considerable size; for you will recollect that fat is very light; so that it must be a large tumor to weigh that. Sir Astley Cooper removed one from the abdomen of a man, that weighed a great deal more. The case is related in the eleventh volume of the Transactions of the Medical and Chirurgical Society, and is accompanied with a figure; and in the engraving the tumor seems almost the size of the man: it was a mass of fat. Sir Astley Cooper weighed it, and it was found to be thirty-seven pounds ten ounces. There was a tumor removed by a French surgeon, from the left hypochondrium, which weighed forty-six pounds: it was only one of eight in the same patient. He had seven others, not quite so large; and it is a circumstance which is sometimes observed in these cases of fatty tumors, that a number of such productions exist in different parts of the body.

Mr. Abernethy describes a tumor under the name of *pancreatic sarcoma*, stating it to consist of masses connected together by the cellular membrane, which in point of colour, figure, and size, resemble the separate masses which constitute the pancreas. He mentions only one case of that tumor, and that was a case which, according to his description, must have been in the lymphatic glands situated under the jaw. Now it has occurred to me to see various instances of tumors, nearly resembling that described by Mr. Abernethy, situated in the angle at the base of the jaw; that is, close to the parotid and submaxillary glands; and the question naturally arises, whether the peculiar character of tumor in this instance can be referred to their local situation; that is, whether they derive their likeness to the structure of the parotid and submaxillary glands from the circumstance of being formed near to them. All I can say is, I have not seen a similar tumor formed in any other part, and that there is a considerable analogy so far as this production can resemble the natural parts of the structure of these glands. The tumors that I now refer to are of a lobulated knotty feel; they seem as if they were composed of distinct masses. They are

hard, approaching in that respect to scirrhus tumors. The skin is loose over them, and the tumor itself is moveable on the parts on which it lies. In this respect you observe they do not resemble scirrhus tumors, which, after a certain time, become fixed to the parts on which they are seated. But these are slow in their growth and development, so that although they may have existed for some years, (and there are instances where they have existed for six, eight, or ten years), still they have the character of looseness in their situation, and the cellular texture surrounding them has not taken on the disease, by which they are discriminated from tumors of a scirrhus nature, although the mere feeling of hardness might lead you to confound them. When you come to examine the texture of the parts after removing them, you find, on making a section, that there is a good deal of likeness to the scirrhus structure, but that the texture is not so tough, nor so hard as scirrhus; it is softer, and instead of being tough and unyielding it will break short off. It has a light amber tint, something like the colour of a raw potatoe; and the tumor, when divided, has a slightly lobulated aspect. Occasionally there is an intermixture in these tumors of streaks and patches of blood, which would lead you to suppose that they had some analogy with tumors of a fungoid character—to fungous hæmatodes, though in no instances that I have seen has there been any real approximation in their nature to that disease. These tumors cannot be checked in their progress by any external applications, or by medicines. You have nothing to do except to remove them; and you had better do that when they are of small size, for they will invariably attain to a considerable magnitude, and they are then so often developed very deeply, and are so intimately connected with the blood-vessels and nerves, and other important parts about the angle of the jaw, that the operation is by no means an easy one.

I was consulted in a case of this kind some years ago by a gentleman, about forty years of age. He had a tumor, of the character that I have mentioned to you, about as large as an orange, seated behind the ramus of the jaw, and advancing over this towards the cheek. It had already existed there between eight and ten years, producing no inconvenience except what arose from its size, and it had now become troublesome on that account, when the jaw was moved. It extended towards the ear, and lifted up the labule of that part, and formed a large mass, which was unpleasant in appearance. I found the skin loose and moveable over it, and I could move the tumor easily on the part on which it lay, but yet I was not quite satisfied that the base was moveable, for in fact the base was so sunk that I could not exactly ascertain the extent of it. I told

him I could suggest nothing but the removal of the tumor; that if he disliked the appearance of the tumor, or found it troublesome, he must have it cut out, but I thought the operation was formidable. He made up his mind to have it taken out, and I removed it accordingly. It was necessary to make two incisions, one extending nearly from the corner of the mouth behind the lobule of the ear, and one transversely to this, like the letter T. By these means I got the surface of the tumor bare, but I had more difficulty in detaching the base. In fact, large arteries entered it, and the division of these produced copious bleeding. In dissecting it I found the base penetrated so deeply that I could not get under it; and I then found it necessary to cut the tumor, and in so doing I perceived that fluid escaped from it. I left behind a part of the tumor, between the angle of the jaw and the pterygoid process; and I thought after I had got rid of a portion of the tumor it would be more easy to extirpate the rest, and I did cut out what seemed to be the remaining part, which went very deep. When I had done this I found there was a prolongation of it inwards, under the angle of the jaw, different in its apparent texture from the part of the tumor that I had removed; that is, it was a soft, bloody looking, friable mass, surrounded by a thin white capsule, and it passed in the interval between the external and internal carotid arteries. I carefully dissected it from the surface of the arteries, and denuded both the internal and external carotids, and took away as much of the tumor as I could. When one is working among vessels of this kind it is not easy to get past them to come to the base of a tumor. I found, by inserting my finger, that the tumor extended to the middle of the vertebral column. I then went behind the pharynx, and broke down the adhesions of the tumor as well as I could, and fancied I had at length got the whole of it out. I then approximated the edges of the wound, and united them by suture. The gentleman lost an immense quantity of blood during the operation, but being a stout hearty man, this was favourable to him. When I examined the tumor, I found it with a texture resembling schirrus; it was of a light yellow colour, and rather firm, but in the centre there was a cavity, and the texture of the tumor assumed a bloody character. There was an intermixture of spots of coagulated lymph, and that part of the tumor that proceeded to the interior of the neck was of a decidedly bloody appearance, which might be set down as fungus hæmatodes, or not distinguishable from it. I shewed this tumor to persons well conversant with the characters of these morbid affections, and they gave an unfavourable opinion respecting the nature and probable issue of the case. They considered

that the texture was allied to fungus hæmatodes, and that those consequences which result from meddling with tumors of that class, would occur. I should have observed that I shewed it to Mr. Wardrop, and he said that he did not apprehend any consequences of that kind. He said it was a sort of tumor he was familiar with, having seen instances of it in the neighbourhood of the jaw, and he thought the patient would do well; and so it turned out. The union went on very favourably. I performed the operation in August 1826, and the patient was well and able to go about his business in less than a fortnight. I have seen him within a few days, and he is perfectly well, never having had any thing like a reproduction of the tumor in the part, nor any other unfavourable consequences. I must observe, that in this case I noticed what I have seen in other cases where I have removed deeply-seated tumors—that the facial nerve was divided, which was followed by paralysis of the muscles of that side of the face; the mouth was drawn aside, and the lower eyelid was affected so that the eye could not be closed. Now, since the time that I have mentioned, the mouth has come nearly straight, but the gentleman is not able to close the eye, as the orbicularis palpebrarum has not recovered its action; but he suffers no other inconvenience.

I remember assisting Mr. Macilwain in removing a tumor of this kind from the face of an elderly gentleman, about 60 years of age. There was an intermixture of a bloody appearance with the mass of the tumor, which led to an unfavourable opinion as to the result of the case. The gentleman died of erysipelas within a fortnight after the operation, which afforded an opportunity of examining the body, and it shewed none of those internal affections which take place in fungus hæmatodes. I have removed tumors similar to this in several other instances, and in all of them the productions had existed for a considerable length of time. They had grown very slowly, and they had not extended to the surrounding parts in the way that schirrous productions do; and they have shewn in no instance any thing like a malignant tendency; so that I have no hesitation in saying that pancreatic sarcoma, constituting the tumors that grow in the situation that I have alluded to, is of an innocent nature.

Mr. Abernethy has a class which he calls *cystic sarcoma*—that is, a tumor in which there are cysts; but the examples he gives consist of a deterioration of particular organs, such as the ovary and testicle, and so forth; which properly ought to be considered under the head of tubercles.

He has a class of *mammary sarcoma*—that is, a tumor in consistence like udder; about which I have nothing to say.

He has a set of tumors under the head of *tuberculated sarcoma*, which are developed in the lymphatic glands, and subsequently followed by the formation of numerous tubercles over the external surface of the body, and by death; after which, the existence of similar productions in a great number of internal organs is discovered—that is, in fact, this tubercular sarcoma is a kind of malignant tumor, according to the description of Mr. Abernethy, leading to the production of new growths in various parts of the body, and terminating life in that way.

Now I have seen a case which, I suppose, should be arranged under the head of malignant sarcoma, which had not that fatal termination; and which I shall mention to you, that you may not suppose too hastily that tumors which multiply themselves in various parts of the body, though attended with serious symptoms, are necessarily fatal; for the truth is, that in many of those diseases that are so important, we must not be too quick in generalizing, laying down rules for practice and acting upon them, as if we understood the subject perfectly. I saw a gentleman who had a tumor on the inner and anterior part of the thigh, just above the knee. This tumor was seen by a surgeon of the very first eminence and most extensive practice, and who had a great general knowledge of his profession. It had formed spontaneously, and had increased rapidly; and he deemed it to be fungus hæmatodes. He represented to the gentleman that it was necessary that his thigh should be removed; and he made arrangements, in consequence of which this gentleman came to London and took lodgings, and a day was appointed for the operation. When the surgeon came to perform it, he hesitated. He had in his mind the fatal termination of numerous cases that appeared to resemble this disease in nature, and he made some excuse to the patient for not doing the operation that day. He subsequently proposed that a consultation should be held, in which four or five of the most eminent surgeons in London met to see the case, and give their opinion as to what was proper. These gentlemen met, and I think they included Sir Everard Home, Mr. Cline, Mr. Abernethy, and one other, beside the gentleman under whose care the patient was; at all events there were five of the most scientific men in London. They decided unanimously that the case was hopeless, and that no operation ought to be performed. The gentleman was advised to go back to the country, and they made up the best story they could to reconcile him to his fate, without telling him in direct terms that he went back to die. But when he got back, he began to see that death was the fate that awaited him. Now he was not quite disposed to acquiesce in this decision, and he determined to have the opinion of two more surgeons.

He requested the advice of Sir Wm. Blizard and myself. We went to the country to see him, and at that time there was a large tumor, of a bright red colour, in the situation that I have mentioned—the inside of the thigh, above the knee. There was also a tumor, the size of an egg, on the back of the pelvis; there was another, about the same size, on the loins, and another situated on the superciliary ridge. On the right or left side of the body (I forget which) there was a great variety of tumors; also on the arms and legs. The gentleman was worn down to the greatest degree of emaciation, by excessive pain and want of rest. He had a small and feeble pulse, profuse and fetid perspiration, got no sleep, and in fact he seemed just going into the grave. For my own part, the case appeared hopeless, and I said so. Sir Wm. Blizard did not go quite so far; he said he thought the case was as nearly desperate as it could be, but that there was a ray of hope if the thigh was removed. This was mentioned to the gentleman, who said that he would let us know the result of his determination in a few days. I heard no more of it; but I found that he had sent for Sir Wm. Blizard and had the limb removed. The loss of the limb was of the greatest service to him; it seemed to remove the immediate source of irritation; he got sleep; in fact, the wound healed up, he got well, and after some time he regained his strength altogether. This operation was performed in the year 1819—that is, about ten years ago. About two years since, the tumor over the eyebrow increased, and that was removed by the medical attendant where he lived. About a year ago, there was a tumor on the fore-arm that had extended considerably; it had attained the size of a walnut, and produced great pain up the whole limb—a kind of nervous affection. He sent for me to take it out. It was deeply seated and closely connected with the ulnar nerve; so much so, indeed, that it almost appeared to be developed in its substance. I had an opportunity of ascertaining that there was a tumor at the back of the pelvis, and one on the lumbar region; and in the same situation I felt a small one under the skin, and a great many tumors on the parts that I have already mentioned. This gentleman was not in a state of robust health, but at all events he was tolerably comfortable, and he owes his life to the operation of Sir W. Blizard, under circumstances which, according to the rules that are generally laid down, would have entirely precluded its performance. I mention this instance to shew that you are not hastily to conclude that these cases, however malignant the character of the affection may appear to be, are altogether out of the reach of surgical aid.

PATHOLOGICAL RESEARCHES
ON
INFLAMMATION OF THE VEINS OF
THE UTERUS, &c.

BY ROBERT LEE, M.D. &c. &c.

[Med. Chir. Trans. Vol. XV. Part. 2.]

— — —

IN our second volume (page 701) we gave an extended abstract of a paper by Mr. Arnott, on the secondary effects of inflammation of the veins. Among the many highly important facts and inferences detailed by that gentleman, was the presence of phlebitis in parturient women as a frequent occurrence, and the cause of some of the obscure morbid phenomena witnessed in that condition. Mr. Arnott's investigations regard the venous system in general; and the evidence he adduces most satisfactorily proves the great importance of its morbid conditions—especially in the production of obscure forms of disease—terminating in or attended with purulent depositions, or other disorganization in distant parts. On the same occasion on which Mr. Arnott's paper was read before the Medico-Chirurgical Society, a case was communicated by Dr. Lee, in which a woman who had died of puerperal fever was found to have inflammation of the uterine and spermatic veins. This was the first of a series of most interesting investigations on uterine phlebitis; and when we consider the obscurity which hangs over many of the most important diseases of the puerperal state, we hail with satisfaction every attempt to elucidate their nature. Dr. Lee's labours in this field of inquiry appear to us highly deserving the attention of the profession on this account, and although we have already given a long abstract in a preceding number (No. 121), from the interesting paper which heads this article, we think it our duty to recur to it, and to present our readers with a more extended analysis of its contents.

With regard to phlegmasia dolens, it may be as well to observe here, that in a former communication to the Med. Chir. Society*,

Dr. Lee brought forward satisfactory evidence in confirmation of the fact which had already been noticed—that in this disease, the trunks and principal branches of the affected extremity are inflamed, but the origin of the inflammation was still a subject of doubt, and its cause remained unaccounted for.

In the paper before us these points are cleared up, and the disputes concerning the nature of this hitherto inexplicable affection are, we hope, set at rest for ever; and we must do Dr. Lee the justice to acknowledge that to him belongs the merit of the discovery of the important pathological fact, that the inflammation of the iliac and femoral veins takes its rise in the uterine branches of the hypogastric veins, and extends from them to the venous trunks of the affected extremity.

The facts brought forward to confirm these views, are, in our opinion, strong enough to convince the most sceptical; and before making any other observations, we shall at once lay them before our readers.

The first case is one of phlegmasia dolens, which proved fatal, and which we shall extract *verbatim*, since it possesses peculiar interest, not only as illustrative of the nature of the disease in question, but as affording, perhaps, the most striking example yet recorded of extensive disorganization of the venous system by inflammation, and of the powers of nature in carrying on the circulation, when even the vena cava itself has in consequence become completely obstructed. We know also of no other case where an opportunity of a post-mortem examination has been afforded of a patient who had twice laboured under phlegmasia dolens, with a considerable interval of time intervening between the two attacks. Independently of these circumstances, this case shews that, if phlegmasia dolens be often a disease of a mild nature, it occasionally assumes a severe character, and puts on one of the worst forms of phlebitis.

"Mrs. Edwards, æt. 35, No. 54, King-Street. 16th of April, 1829, was delivered of her second child, three weeks ago, after a natural labour, and on the 9th inst. was attacked suddenly with pain in the calf of the right leg, and loss of power in the whole right inferior extremity.

"On the 13th, a considerable swelling,

* A contribution to the Pathology of Phlegmasia Dolens, by Robert Lee, M.D.—Med. Chir. Trans. Vol. XV. Part I.

without discolouration, had taken place from the ham to the foot, and great tenderness was experienced along the inner surface of the thigh to the groin.

"The extremity is now universally swollen, painful, and deprived of all power of motion. The temperature along the inner surface of the limb is increased; the integuments are pale and glistening, and do not pit upon pressure. There is no pain in the hypogastrium, but pressure along the course of the crural vessels excites great suffering, and the vein from the groin to the middle of the thigh is indurated, enlarged, and exquisitely sensible. There is also great sensibility in the ham, and along the inner surface of the leg to the ankle, where some branches of the superficial veins are hard and painful on pressure. Pulse 80; tongue much loaded; thirst; bowels open. There was no rigor, or symptom of pyrexia, at the invasion of the disease. She states that the veins of the right extremity were more distended during pregnancy than those of the left.

"Twelve years ago, after the birth of her first child, the patient and her relatives report, that she experienced an attack similar to the present, in the same limb, and that it remained in a weak condition for several months afterwards, but ultimately recovered its natural size and power.

"April 18th.—The tension and increased heat along the inner surface of the limb are somewhat diminished, but the pain continues in the course of the vessels.

"May 1st.—Affection declining. The femoral vein cannot now be felt, but there is still a sense of tenderness in its course down the thigh; no pitting on pressure. She has suffered, during three or four days, considerable uneasiness between the umbilicus and pubis, as well as in the loins, and has had rigors, with quick pulse, loaded tongue, and thirst. The abdomen is soft, but tender on pressure around the umbilicus.

"9th.—The swelling of the limb is nearly gone, as is the tenderness in the course of the femoral vessels. For several days past, she has experienced attacks of acute pain in the umbilical region, loins, and back, which have assumed a regular intermittent form. Every afternoon there has been a violent rigor, of an hour's duration, followed by increased heat and profuse perspiration. In the course of the last and preceding nights, there was slight delirium. The skin is now hot and dry; the pulse 125; the tongue brown and parched; bowels open.

"The abdomen is neither tense nor swollen. On pressing around the umbilicus, she complains of a deep-seated feeling of soreness. A strong vibratory motion, corresponding with the pulsations of the heart, is perceived in the epigastrium.

"21st.—The febrile attacks gradually declined in severity, and she appeared to reco-

ver, until yesterday, when she had a long and violent fit of cold shivering. The countenance is now expressive of great anxiety, and the pulse extremely quick and feeble. There remains no visible trace of the affection of the lower extremity.

"23d.—Has been vomiting ever since yesterday, at intervals of half an hour. Complains of great pain in the left side, increased upon taking a deep inspiration. The pulsation in the epigastrium diminished, although it is still clearly perceived. Pulse 120, and soft.

"24th.—Symptoms continue without alleviation. Has had a severe shivering fit of long duration. Skin hot and dry; pulse 140; tongue brown and parched; diarrhoea. The pulsation in the epigastrium has entirely disappeared; the pain in the left side of the thorax is diminished; but the respiration is hurried, and there is frequent cough. Great prostration of strength. Surface of the body has assumed a peculiar sallowness. She has been delirious in the night, but is now perfectly conscious when roused.

"The conjunctiva of the right eye has suddenly become of a deep red colour, and so much swollen that the eyelids cannot be closed. The cornea is dull, she makes little complaint of pain in the eye, and there is no intolerance of light. The vomiting has ceased.

"25th.—Has again had repeated attacks of vomiting. Debility rapidly increasing; respiration hurried; incessant hacking cough; pulse 140, extremely feeble; surface of the body cold and clammy; the tongue and teeth covered with dark sordes; diarrhoea. The left eye has also become red and swollen, without much increased sensibility.

"26th.—Great debility; when undisturbed she is delirious, but is conscious when roused, and complains of pain in the left side of the chest. Pulse above 140. Tongue black and dry. Conjunctiva of left eye also affected with swelling and intense redness. The cornea is dull, and shreds of lymph appear to have been effused over the left iris.

"28th.—Had so violent a rigor in the afternoon that the bed shook under her. She is now completely insensible. The eyes are red and swollen, and there is a copious secretion of an opaque fluid from their surface and from the eye-lids, which cannot be closed. The respiration hurried. Pulse 140.

"June 2d.—Great debility. A red puffy swelling has suddenly appeared over the right elbow-joint. Tongue dry and black; diarrhoea; frequent, or rather constant, wandering, except when spoken to, when she answers questions distinctly, and complains only of pain in the chest, with difficult respiration and cough.

"10th.—Little change has taken place in the symptoms; but she has become much weaker. The vision is lost, but the hearing

is perfect, and she makes no complaint of pain in any part of the body.

"15th.—Died this morning.

"*Morbid Appearances on examining the Body of Sarah Edwards on the 16th June.*—Present, Drs. Sims and Locock.

"*Thorax.*—In its left cavity were contained upwards of two pints of a thin purulent fluid, and extensive recent adhesions existed between the pleura covering the lower margin of the superior lobe, and the pleura costalis. The surface of the inferior lobe was coated with a thick layer of flocculent coagulated lymph, as was a corresponding part of the pleura costalis. The substance of this lobe was of a dark colour, approaching to black, and soft in texture, so as to be readily broken down with the fingers. In its centre about an ounce of thick cream-coloured pus was found deposited in the dark-coloured and softened lung. This was not contained in any cyst or membrane, but infiltrated into the pulmonary tissue.

"In the right cavity of the chest, recent adhesions also existed at the inferior part. A considerable portion of the right inferior lobe was entirely changed from the healthy structure, being converted into a dense, solid, dark red-coloured mass. On the anterior surface of this lobe the pleura was elevated, as if by a hard irregular tumor, but when cut into, no pus escaped from this part, and it presented only the appearance of the surrounding portions of lung with a greater degree of condensation.

"*Vena cava inferior.*—Coats of the vessel considerably thickened, and the internal, where visible, of a scarlet colour; its whole cavity occupied by a coagulum, distending it to its utmost extent, and terminating in a loose pointed extremity about an inch below the entrance of the vena cava hepatica. The coagulum covered with a membranous-like investiture of a bright red colour, throughout firmly, and in many places inseparably, adherent to the inner lining of the vein; the substance within it varied in consistence and colour; in some parts it presented the appearance of coagulable lymph, in others it was a pultaceous dull yellow mass, made up apparently of pus and lymph blended together. The exterior of the firmer portions were separated into layers, which gradually disappeared as they approached the centre. The mouths of all the veins emptying themselves into the cava were sealed up, the emulgents excepted, the coagulum near the entrance of these vessels hanging loosely within the cava.

"*Left common iliac and its branches.*—Its interior plugged up with a continuation of the coagulum from the cava, and differing in no respect from it either as to consistence, colour, or the firmness of its adhesions to the inner tunic of the vein; it was continued

beyond the entrance of the internal iliac, (which it completely closed,) and terminated in a pointed extremity about the middle of the external iliac: neither the remainder of this vessel nor the femoral vein exhibited any morbid changes. The internal iliac was much contracted, and lined with a thick adventitious membrane.

"*Right common iliac and its branches.*—This vessel was contracted to more than one-half its natural size; it was firm to the touch, and of a greyish blue colour; to its internal coat adhered an adventitious membrane, of the same colour, containing within it a firm coagulum, made up of thin layers of dense lymph. The internal iliac was rendered quite impervious by dense dark-coloured bluish membranes, and at its entrance into the common iliac was converted into a solid cord.

"The contracted external iliac contained within it a soft yellowish coagulum, similar to the one in the cava; its coats were three or four times their natural thickness, and lined with dark-coloured membranous layers.

"The femoral vein, from Poupart's ligament to the middle of the thigh, was diminished in size, and almost inseparable from the artery. Its tunics were thickened, and its interior coated with a dense membrane surrounding a solid purple coagulum strongly adherent to it. The superficial and deep femoral veins were in a similar condition, and the saphena major and minor differed from the femoral veins only in the size of the coagulum they contained, which was slender, and had formed no adhesions with the layers of lymph lining their cavity.

"The cellular membrane and other textures of the limb were in a perfectly healthy condition, and in size and appearance there was externally no visible difference between the two extremities."

The second case related by Dr. Lee offers the clearest testimony of the truth of his views regarding the nature and origin of phlegmasia dolens. The subject of it died of tubercular phthisis about three months after her confinement. On dissection the uterine plexus and trunks of both hypogastric veins were found alike disorganized; on the left side the inflammation had extended to the iliac and femoral veins, which were thereby rendered impervious, and the return of blood being prevented, the limb, as a consequence, had become swollen and painful; in short, it had been affected with phlegmasia dolens. The same morbid appearances presented themselves in the uterine plexus and trunk of the right hypogastric vein, which, by an anomalous course, terminated

in the left common iliac. The veins returning the blood from the right inferior extremity, viz. the common and external iliac, were healthy, and they owed their immunity from inflammation without doubt to the singular course of the right hypogastric vein. The circulation in the right iliac veins being unobstructed, the corresponding extremity, as was to be expected, shewed none of the signs of phlegmasia dolens.

In the third case both legs were affected, and the veins of both on dissection were found obstructed by inflammation, which had extended for some distance even into the vena cava.

Accurate representations of the morbid appearances of the veins in the two last cases, are given at the end of the volume, and, when the paper was read, a beautiful drawing of those in the first case was exhibited, as well as preparations of all the inflamed veins which Dr. Lee had met with whilst investigating the subject.

In the 4th, 5th, and 6th cases, though the fact of the existence of inflammation of the veins was not demonstrable by dissection, we have the strongest presumptive evidence which symptoms can offer, that they were so affected, and the extremities presented all the characteristic signs of phlegmasia dolens.

It has been objected that the cases published by Dr. Lee are not genuine examples of phlegmasia dolens, since they differ from this disease both in the severity of their symptoms, and in the appearance presented by the affected limbs. We hold the latter objection to be of no force, for Dr. Lee's own testimony respecting the exterior character of the complaint is corroborated by that of many of his professional friends; and besides this, if his descriptions be compared with those of the best writers on phlegmasia dolens, they will be found to agree with them in every respect: but even supposing that were not the case, we are of opinion that minor shades of difference in the appearance of the swollen extremity would be of no consequence, since they might depend on the strength and age of the patient, on the condition of the integuments, and on the mode of attack. If the last be sudden and violent, and the integuments be firm and unyielding, the pain of course will be greater, and the

swelling more characteristic, than when the skin is flaccid, or when, in consequence of a slower obliteration of the veins, the effusion into the cellular substance has taken place more gradually. Under the latter circumstances, if we except the pain in the course of the vessels, the limb will not differ from an anasarcaous one; nor will it do so in the latter stages of the complaint, whatever may have been its peculiar character at the earlier periods. In some instances, this anasarcaous condition of the limb, and a varicose state of the veins, will continue for a period of years. In a case Dr. Lee gave us an opportunity of witnessing, three years had elapsed from the attack which had affected both extremities: at the time we saw the patient, these were swollen and weak, and the superficial veins of both were varicose. The peculiarity in this instance, however, was the enormous size of the superficial veins of the abdomen, which were seen running in a tortuous direction under the integuments, as large in appearance as the femoral or iliac veins, and there is every reason to suppose that they were thus enlarged to assist in carrying on the circulation, the venous trunks of the extremities having been obliterated by inflammation.

As regards the severity of the symptoms in Dr. Lee's cases, we must confess we were at first staggered, though be it remembered, that he is not the first who has met with fatal cases of phlegmasia dolens: we had considered it as almost always a disease of a mild nature, scarcely requiring medical interposition, and very rarely terminating unfavourably: such is still the opinion of many, but is not this opinion the result rather of preconceived notions than of experience, and is it not probable that the idea generally prevalent of its innocuous nature, may have deterred many from publishing the unfortunate results of their practice? As far as we ourselves are concerned, Dr. Lee's cases and arguments have convinced us of our error. We admit also that he has established the fact of phlegmasia dolens originating in the uterine veins, or, in other words, that it is one of the consequences of uterine phlebitis. Why uterine phlebitis should not always be followed by phlegmasia dolens, is explained by the fact of the sper-

matic veins alone being for the most part inflamed, or by the inflammation, if it attacks the hypogastric veins, being arrested at the termination of these veins in the iliacs. Why phlegmasia dolens should not always be accompanied with the graver symptoms of uterine phlebitis, is a question more difficult of solution, but the same difficulty presents itself in the explanation of the varieties of many other diseases. Much, of course, will depend on the degree and extent of the inflammation. It seems absolutely necessary to the production of phlegmasia dolens, that the inflammation should affect the great veins of the extremities: now we know that when veins become inflamed, the inflammation is prone to extend in a direction contrary to the circulation; hence one of the reasons of phlegmasia dolens following an attack of uterine phlebitis: we also know that the inflammation is apt to be arrested at the junction of branches with their trunks; consequently it may exist in the uterine veins without the production of the swelled leg, the iliac and femoral veins remaining unaffected.

The circumstance most difficult of explanation is, the comparative mildness of the symptoms in the generality of cases of phlegmasia dolens, where so important a system of vessels as that of the veins is implicated in disease. If we might hazard a conjecture on the subject, we should say that in the ordinary cases of phlegmasia dolens, the inflammation runs rapidly from the uterus to the common iliacs, which it obliterates or seals up by an effusion of lymph before any of the morbid products of inflammation can become mixed with the circulating blood; and to give weight to this opinion, we would cite the second case, where, though the veins were extensively disorganized, no symptoms of phlebitis ensued: the reason was apparent on dissection, the left common iliac into which both hypogastric veins emptied themselves having been found converted into an impervious cord. The first case and the seventh might be brought forward to prove, that the severity of the symptoms is owing to the extension of the inflammation into the vena cava without producing entire obliteration of its cavity, and thereby preventing the mor-

bid secretion from entering into the mass of blood.

We may sum up these remarks by observing, that the disease in question will be, like all others, modified by the constitution of the patient, by the degree of inflammation, and by the rapidity of its march; and that its fatal effects will be most generally averted by the sudden obliteration of the inflamed veins.

In addition to the cases he has related, Dr. Lee adduces a body of evidence from the writings of others, to substantiate his own. The authors, however, whom he has quoted, though they shew the existence of inflammation in the veins, seem to have been quite in the dark respecting its origin in the venous system of the uterus.

Dr. Lee having by numerous facts and deductions rendered it apparent that phlegmasia dolens is never present unless there be obstruction in consequence of inflammation of the veins returning the blood from the affected extremity, it behoves those who still doubt the correctness of his views, to bring forward evidence equally satisfactory, that phlegmasia dolens can exist, these veins remaining in a state of immunity from disease. Until then we shall not allow the absurd theories respecting this disease—theories which, by the way, never offered even any plausible explanation of its phenomena—to regain possession of our minds, but shall remain convinced of the truth of the facts contained in the paper before us, both because we can rely on their authenticity, and because they offer a ready solution of all the difficulties in which the question has been heretofore involved.

This point settled, we come to what we consider one of the most important parts of the paper, where Dr. Lee shews the connexion of phlegmasia dolens with uterine phlebitis. He commences by observing, that

“All the different authors who have treated of phlegmasia dolens describe it as commencing, in the great majority of cases, subsequent to the tenth day after parturition, with symptoms of uterine irritation, and constitutional disturbance of a low nervous character, and with pain and swelling in one extremity only. They have assigned various reasons for these remarkable peculiari-

ties in the period and mode of development of the disease, as pressure of the gravid uterus on the iliac veins during gestation, the change in the distribution of the blood from the sudden removal of this pressure, exposure of the extremity to cold, suppression of the lochial discharge, &c. all of which, however, taken singly, or combined, are insufficient to account for the phenomena; and the occurrence of the disease after menstruation and abortion proves that these causes are not necessary for its production. The facts which have now been stated afford a more satisfactory explanation of these phenomena, and shew, that if inflammation be excited in the orifices of the uterine veins, it may spread along these to the iliac and femoral veins, and by the morbid changes induced in them, give rise to all the subsequent symptoms.

"The mode of development and extension of the inflammation from the uterine to the iliac and femoral veins of the affected extremity, will be best understood by a concise statement of the principal facts relating to uterine phlebitis, of which phlegmasia dolens must now be considered as merely one of the remote consequences."

From the statement which follows, it would appear that, by the separation of the placenta, the orifices of the uterine veins are left in a state favourable to the production of inflammation; which being once excited, extends with greater or less rapidity along the continuous membrane of these vessels to the spermatic or hypogastric veins, and from them to the vena cava and its principal branches, returning the blood from the lower extremities.

The effects of inflammation in these veins, are the formation of adventitious membranes on their inner surfaces, and the deposition of coagula of lymph, or of purulent matter, within their cavities.

"The inflammation may be limited to the veins, but not unfrequently the muscular tissue of the uterus contiguous to them participates in the inflammation, and becomes of a dark-red or blackish-brown colour, and so soft in its consistence as to be readily torn with the fingers. The peritoneal covering may be also affected, and the usual consequences of puerperal peritonitis will then ensue."

The veins returning the blood from the uterus may be either wholly or in part inflamed; it is remarkable, however, that

generally the spermatic veins alone are attacked, and for the most part the one only on the side of the uterus to which the placenta had been adherent. The inflammation may be limited to a small portion of the vessel, or extend through its whole course. If the hypogastric veins be affected, it happens commonly that the inflammation is also confined to one of these vessels; they are, however, less liable to the disease than the spermatics; and to this circumstance may be ascribed the comparatively rare occurrence of phlegmasia dolens as a consequence of uterine phlebitis, which we believe to be of more frequent occurrence than is generally imagined; and we are confirmed in this belief by the fact of the uterine veins being so often found obliterated in old women who have died of other diseases.

The causes of uterine phlebitis are mechanical injury, decomposition of portions of placenta retained in the uterus, the application of cold, contagion, &c.

The invasion of the disease is uncertain; it may attack the patient soon after delivery, or even so late as the twentieth day. Its duration is equally indeterminate.

With regard to the symptoms, they will vary according to the tissue affected. If the veins only be implicated, there is often either no pain or a dull heavy pain only, about the region of the uterus. If the substance of the uterus be inflamed, this organ is felt above the pubes, and is acutely painful on pressure.

"The constitutional symptoms of uterine phlebitis, and the important alterations which take place in the structure of the brain, lungs, and other internal organs, and also in the synovial, serous, and cellular membranes, are often so peculiar and characteristic, that it is the more remarkable this disease should have been so long overlooked by pathological inquirers."

These symptoms are so accurately described in the cases related by Dr. Lee, in illustration of his remarks, that we cannot do better than refer to them. The seventh case in particular, is well deserving an attentive perusal. The subject of it was attacked with phlebitis subsequent to parturition. The disease proved fatal;

and on dissection, the uterine and right spermatic veins were found highly inflamed and disorganized, and the effects of inflammation were also apparent in the vena cava and right emulgent vein. The lungs were affected with gangrene, and pneumonia-thorax existed on the right side of the chest.

Six other cases are given, and all of them are interesting, as exhibiting different varieties of an affection which has never been thoroughly investigated, and which, in this country, has as yet been scarcely noticed by pathologists. Recent experience has induced Dr. Lee to believe that many of the fatal disorders of puerperal women which have usually been comprehended under the vague designation of puerperal fever, or peritonitis, must be referred to uterine phlebitis.

"Inflammation of the uterus and its appendages," he adds, "may be considered as essentially the cause of all the destructive febrile affections which follow parturition; and the various forms they assume, inflammatory, congestive, or typhoid, will probably, in a great measure, be found to depend on the serous, muscular, or venous tissue of the organ having become affected."

We have extended our remarks to so great a length, that we can only slightly notice the remaining part of the paper, in which Dr. Lee presents us with the additional fact of the occurrence of inflammation of the veins of the uterus in malignant diseases of that organ. The 14th case is one of inflammation of the uterine veins, with carcinomatous ulceration of the os and cervix uteri; and the 15th is an example of inflammation of the left iliac and femoral veins, with phagedenic ulceration of the womb. In the last case, phlegmasia dolens had attacked the left inferior extremity; and from it, and from another recorded in the sixth volume of the *Archives Générales de Médecine*, it would appear that this affection is produced in the same manner as it is after parturition—viz. by the extension of inflammation to the iliac veins.

At a late meeting of the Medical and Chirurgical Society, Mr. Lawrence related an interesting case in confirmation of the above fact, and where phlegmasia dolens was caused by inflammation of the veins of

the lower extremity, excited by malignant ulceration of the cervix uteri.

In a man who died of cancer of the rectum in St. Bartholomew's Hospital, the same gentleman observed the iliac veins inflamed and obstructed; and at the meeting we have just alluded to, the case of a young man was read, in whom symptoms of phlegmasia dolens had manifested themselves during life. The post mortem examination shewed that the affection was produced by obstruction of the great veins of the limb, in consequence of inflammation; the veins of the pelvis were equally involved in the disease, and no cause could be assigned for this condition of the vessels, till it was discovered that the lower part of the rectum was extensively ulcerated.

From the above facts it is therefore evident that inflammation may be excited in the veins of the pelvis in both sexes, by diseases of the neighbouring organs; and that from them it may be propagated to the principal veins of the lower extremities, and give rise to the phenomena observed in phlegmasia dolens.

In conclusion we would observe, that whatever difference of opinion may exist as to the inferences Dr. Lee has drawn—and we believe correctly drawn—from his facts, the facts themselves must be regarded as highly important. They prove that inflammation of the venous system of the uterus is of frequent occurrence, not only subsequent to parturition, but also in malignant diseases of that organ; and that the symptoms it gives rise to present, from causes not easy to explain, many varieties of character—in some instances being so mild as scarcely to require medical aid, in others so grave as to bid defiance to all the resources of our art.

We particularly recommend the perusal of the cases and dissections in Dr. Lee's paper to our readers—they are all of them interesting, and are valuable contributions to the scanty stock of knowledge we possess of the diseases of the venous system.

STATE OF THE PROFESSION—
PHYSICIANS.

*To the Editor of the London Medical
Gazette.*

SIR,

I RECEIVED much pleasure in the perusal of a paper by "A Country Practitioner," in a recent number of the *Gazette*. That was a business-like letter: it acknowledges a crying evil in our profession, and it seeks a direct and appreciable remedy. That letter originated from two preceding, of which the first was subscribed "Mediculus." I hoped that as "Mediculus" possessed some conceptions of the disorders of our profession, he would prescribe the appropriate remedies; but in a succeeding communication he has left the terram firmam to soar into the clouds.

Δεπτολογεῖν ἤδη ζητεῖ, καὶ περὶ καπνῶν
στερολεσχεῖν.

That our profession labours under great degradation, is evident, not only to the "Country Practitioner" and myself, but, doubtless, to great numbers who practise in it. *The* most striking illustration of this position is to be found in the existence of that *Journal* which yours was instituted to oppose. I believe that no learned profession, in any era of literature, ever tolerated and patronized such a production, except the medical body of these days; yet from a conviction that that *Journal* naturally sprung from the corruption of our corps, I have never felt that undivided contempt for it which many have uniformly experienced. But I have wished a thousand times, that a spirit of reform had been manifested and exerted by a sober-minded, discriminating, well-bred, and learned man—by some honest fellow, who really loved his profession. I wish I could see, as some declare *they* see, that even that *Journal* has been productive of good; but I greatly fear that it will serve to aggravate the very evil which it professes to combat—the corruption of the medical body. Heavens! there must indeed be need of reform, when *such* a reformer can boast of *any* disciples! It is not my intention to vent a philippic against a production which I should never have thought of mentioning,

save by the way of illustration. I assert the great prostration of our character as a profession, and my chief proof is the existence of a most profligate and plebeian professional *Journal*. Yet I will take this opportunity to express a surprise and a regret, which I share with thousands of my medical brethren, that an undue and monstrous consequence has been conferred on that work, by the very notice and opposition which it has received.

But to return to the *gravamina medicinæ*—whose existence cannot be denied—whose remedy is the problem to be solved. The "Country Practitioner" calls for legislation, and who will not second his call? Yet legislation, to be efficient, presupposes a certain degree and kind of *morale* in its objects. Legislation alone never has done, nor ever will do, all that is necessary to reform any body of men. I never could be convinced of the truth of Jeremy-Benthamism, which is, I presume, being interpreted, the doctrine that the miseries of the governed are to be laid wholly at the door of their governors; since by the Jeremy-Benthamic process any government may learn to make its subjects wise, good, and happy. Indeed this deduction has been plainly, and in so many words, conceded to me by the great apostle of Jeremy-Benthamism—by that gentleman who, it is said, translated into terrestrial English the celestial lucubrations of Mr. Bentham.

Now, sir, I cannot blind myself to the corruption of the medical body, which is evident in all directions. The company of apothecaries, no man can doubt, desire to purify their department of the profession; but their powers can only be wielded through the medium of the law. In answer to the suggestion and proffer of the "Country Practitioner," they have declared that the law is not available for the flagrant case which he denounced to them. I am utterly ignorant of law; and cannot, therefore, decide on the correctness of their assertion. But it is very evident to me that if the profession did what it ought—if the practitioners who reside in the neighbourhood of the huxter who is denounced—would, one and all, decline to meet a man who has the solitary merit of bringing fees to their pockets, the society of apothecaries,

would not be required to interfere. The fellow must, essentially, sink into the shades. Is there, or is there not, then, a hope to be cherished by us that *we* shall live to see the medical body pure and dignified? I say with reluctance, but with sincerity, that I can conceive none. The biography of the members in our art, in every form thereof—the facility which is afforded by the practice of medicine to deceit—to false assumption of merit, and to the concealment of professional error—convince me that ours can never become a high-minded and generous corps. Yet some palliation of unavoidable evil is not impossible; and the improving education of the young men, “who read for” (dis-) “orders,” is a guarantee that the future generation of British practitioners will have more of *professional* character than the past. I hold that the company of apothecaries, against which so much vituperation has been hurled, deserve well of their country, for that particular law which demands of their candidates an acquaintance with the Latin tongue. The rich stores of the magnanimous, which this knowledge will render accessible, it must be hoped will not be presented to medical students in vain. If I believe any thing, I believe most firmly that the more any man is imbued with a knowledge of the ancient classics, the more will he partake of those generous and pure sentiments which ought eminently to characterize the practitioner of the healing art. But as the medical world now goes, artifice and trickery are the passports to business and money. Physician, surgeon, apothecary, midwife; all are manœuvring for notoriety and employment.

The fastidious sentiments which animate the gentlemen at the bar, should pervade the breasts of the mass of physicians. During a circuit, the barrister is not permitted, by the regulations of his order, to “hug” the solicitor. But what perpetual hugging of the apothecary is manifested by the physician! I have seen it, and condemned it, in the city and the country; in the metropolis and the provinces. I have known such a man as he, who is denounced by the “country practitioner,” courted, invited, saluted, familiarly treated by *genuine* physicians. This conduct assuredly lowers the ancient respectability of the physician, and, in the long run, I imagine, it must affect his pocket.

The educated general practitioner must feel disgust at such proceedings, and he must vow to himself, as I have vowed, that bating the consultation with a physician, which his conscience pronounces to be needful, he will never encounter one professionally, when, without personality, he can escape the interview. There have been physicians who have even paid court to the editor of that journal which has already been mentioned. Think of that! It is only by fairly looking in the face of our gravamina, by confessing and decrying them, that we can effect the respectability of our art, and annihilate the systematic contempt for its professors, which it is the interest of some persons, pretending to professional feeling, to foster and augment. Of the manœuvres of the physician to obtain repute, one very common and very pitiful is, to write a book; not with a view of instructing the profession, but to captivate the crowd; not, as in days of yore, to publish his experience, or the results of profound and philosophic investigation, but to induce in the minds of those patients who labour under particular disorders an idea that he has made their disease the subject of his peculiar research. Hence a treatise by the young doctor on gout, to tell with the fashionable and luxurious; or on rheumatism, because it is so rife a malady; or on consumption, because it is the disorder most dreaded in families; or on scrofula, for it is the great complaint in England; or on disorders of the kidneys and bladder, if he happen to settle in a district infested with calculous maladies. I have known a young physician leave at the door of the apothecary his card and his inaugural thesis, “with the author’s compts.” superscribed. The stethoscope has been a successful weapon in the hands of many a finessing physician, who really does not possess the patience nor love of science necessary to the mastership of that important instrument. But the most nauseating specimens of puffing are to be found in private companies, at the dinner table, as soon as the glass has circulated a little: if there be a young physician present, you are certain to hear some professional egotism and technical palaver. There are as many exceptions as you, Mr. Editor, may demand to be made—but this is the general rule; to smell of the shop,

is the common failing. I have not room to touch on the faults of apothecaries—or general practitioners, which I defer to a subsequent communication.

A SURGEON, APOTHECARY, AND
MAN-MIDWIFE.

AN ILLUSTRATION

OF A

FATAL SPECIES OF SCARLATINA,

Lately prevalent at Plymouth.

By EDWARD BLACKMORE, M.D.

Physician to the Public Dispensary.

THE subject of the present communication is an impressive instance of the diversity remarkable in the constitution of particular diseases at various periods, and of the multifarious sources of danger involved in them. The scarlet fever has not hitherto prevailed extensively among the general population, but has very much confined its attacks to the better classes; in whom, likewise, the most extreme mortality has taken place. Of seven cases which have come under the personal observation of the writer, one only was fatal; whereas, in the family of a surgeon-apothecary of this place, four who were attacked all perished, and in another family two died.

The absence of dangerous symptoms in the outset of the recent epidemic; its insidious progress, its rapid and unexpected fatal termination, with the obscurity which has confessedly overhung the causes of its high mortality, and the discrepancy of medical opinion here on the best method of obviating its ravages, concur to render the subsequent case not undeserving of consideration.

A. May, a fine girl, nearly three years of age, complained on the 25th of March of pain in the head, with retching, costiveness, and high fever, which was supposed by the mother to be the scarlet fever. Three days hereafter the fever is said to have "turned;" no sensible pain or difficulty in swallowing was remarked up to the fifth day, but the head complaint continued, with some delirium on this day. Costiveness, and perfect inappetency for food. Some purgative medicine alone had been

used. On the sixth day the case was first seen by a surgeon-apothecary, by whose directions a purgative was given, and a blister applied around the throat, which was remarked to be slightly ulcerated; no alarming symptom, however, presented itself. I saw her on the eighth day of the malady; slight fever then subsisted; the face was tumid, and of a purplish hue; some ichorous mucus flowed from the nostrils. Two ulcers were seen behind the tonsils, which were coated with viscid purulent mucus, devoid of bad fœtor, and of innocuous aspect. She was disposed to slight stupor, but perfectly sensible, and struggled in the nurse's arms on being disturbed. Nothing appeared to forbid a hopeful prognosis. When seen again two days afterwards, she was in the act of dying. Stupor had come on shortly after my previous visit; the respiration became obstructed; dark concrete sanious mucus filled the nostrils, and much fœtor was exhaled from the throat. Her whole aspect was that of one dying of putrid sore throat, with oppressed brain and lungs.

Dissection 40 hours P.M.—The abdomen and legs were very livid, with petechiæ; no tumidity; much gummy ichor in the nostrils. In the chest no pleuritic adhesions; no serum. The lungs very much engorged and dense with black fluid blood, particularly the left lung, but no extravasation of blood; no mucus in the air cells. The mucous membrane of the large bronchi stained by the congested blood; no vestige of confined inflammation. The right side of the heart was distended with a large mass of fibrine. Some fluid black blood remained in the left auricle and ventricle. The liver was large and healthy; the gall-bladder full of green bile. The spleen, intestines, and stomach, were natural, except that a tint of vascularity appeared on the cardiac portion of the mucous coat of the latter organ. The brain was engorged with black blood, and its ventricles held $\frac{3}{4}$ ss. of bloody serum: its substance was dense. In the palate, deep behind the tonsils, on the verge of the posterior nares, were seated two large ulcers, covered with very fetid matter, like soft rotten cheese, but with no positive vestige of gangrene. The larynx and trachea were healthy. Marvellous as it may appear, the present is the only instance, in so far as the writer can learn,

where an anatomical inspection has taken place.

With regard to the mode of death, and its immediate causes, it may be observed that a rapid transition from a state of innocuous disorder to one of imminent danger, (which has characterized all the fatal cases within the writer's knowledge), seldom or never happens in the mode of direct debility, but is to be referred on the soundest physiological principles to the oppression of some vital organ. That such was the occasion of the fatal issue in the present case is determined by the history and the dissection. The remote causes of the coma, and the suffocation, were, I presume, 1st, the high eruption in fever, and next the fetid caseous pus which exuded from the ulcers in the throat, and obstructed the nostrils. Not that I conceive the local disease to have been a merely mechanical impediment to respiration; the morbid secretions may have had a poisonous influence on the pulmonic nerves, and thus have suspended the vital action in the lungs. As all the fatal cases exhibited similar phenomena with the present except that in a few there was less of febrile excitement and earlier stupor, analogous to the congestive typhus, it may be concluded that in all the immediate causes of death were the same.

If this exposition of the pathology of the recent malady be correct, the most successful mode of treatment cannot be obscure, *i. e.* decisive anti-febrile remedies in the outset, and towards the end severe counter irritation on the skin, with emetics. The capsicum gargle has been deemed by some to be of specific virtue, and blood-letting to be injurious; but in the writer's experience the deep corroding ulceration in the throat has been always attended by strong febrile action, and been checked by general evacuants. Moreover, the unquestionable oppression of internal organs, by sanguineous congestion, most certainly contra-indicates the use of excitants, such as were specific in the malignant ulcerous sore throat of former times.

Plymouth, April 12, 1830.

OBSERVATIONS

ON THE

REMOVAL OF THE CHRYSTALLINE LENS.

By RICHARD MIDDLEMORE, Esq.

Assistant Surgeon, Birmingham Eye Infirmary.

—

In my last communication I objected to the early extraction of the crystalline lens; first, because such an operation was generally unnecessary; and, secondly, because it was, in many instances, calculated to be highly injurious. I represented that when a section of the cornea, and wound of the capsule only took place, producing a displacement of the lens, such an occurrence in young subjects was not commonly succeeded by any very serious consequences, on account of the softness of the lens, and the activity of absorption. I attempted to shew, that when the same accident occurred at a more advanced period of life, an early operation only became necessary from some peculiar position of the displaced lens, or some morbid action with which the eye had been previously affected. I shall on the present occasion endeavour to point out those circumstances which render such an operation requisite.

The crystalline lens may be forced by accidental violence directly backwards into the substance of the vitreous humour; it may be urged against the retina and choroid at any part of the interior circumference of the eye-ball. After having quitted its capsule it may push the iris forwards, gently pressing it against the retinal surface of the cornea; it may remain balanced against the floating margin of the iris, intermediate between the anterior and the posterior chambers; or it may pass through the pupil into the anterior chamber, and remain supported by the loose border of the iris. In the first form of dislocation, the irritation occasioned by the intrusion of the lens will not be very important, but the degree of violence requisite to impact it in such a situation, and the laceration of the cells of the vitreous humour, will, of course, give rise to a high degree of inflammation. If active antiphlogistic remedies and mercury be early and judiciously employed, the eye may be, to a certain extent, restored; the vitreous

and crystalline humours may be absorbed, and their place supplied by an augmented secretion of aqueous humour; or the vitreous humour may remain, and the lens assume the third or fifth form of dislocation. In the second kind of displacement it is sometimes necessary to perform an operation at a comparatively early period. When the lens is urged against the retina—when that delicate membrane, with the choroid, is compressed between the hard margin of the crystalline and the concave surface of the sclerotica—we have not merely to contend with an inflammation, the immediate effect of the blow or injury, but also a second cause, which is producing the same effect. If such a state of things exist, the patient will complain of tormenting agony; the eye-ball, the head and face, on the side of the affected organ, will be the seat of darting and throbbing pain. Iritis, and inflammation of the deeper textures, will be present; and if the eye be attentively examined, a portion of the circumference of the lens may be seen through the pupil, clearly pointing out the nature of the dislocation and the source of the patient's sufferings. If a couching-needle be now introduced through the cornea (as for keratonyxis), and the lens gently raised, or if a minute section of the cornea be made, a small hook introduced, and the lens elevated to its proper situation, every acute symptom will be instantly relieved, and the patient's advancement towards recovery be progressively rapid, with the assistance of the customary remedies for the removal of inflammation of the deep-seated textures. I object to the extraction of the lens in such cases, because it is an operation which an eye acutely inflamed is not in a fit condition to bear, and prefer relieving the urgent symptoms by this trivial operation, leaving the cataract, which is likely to remain, for subsequent treatment.

Should the lens, on deserting its capsule, urge the iris forwards against the retinal surface of the cornea, it would be desirable, as soon as the acute symptoms have been subdued (if no appearance of absorption be discovered), to pass a fine couching-needle through the sclerotica, and with very gentle motion tear it in various directions; bearing in mind, that it would be better to repeat the operation than incur the risk of exciting a high degree of inflammation by

persevering attempts to comminute the whole of the lens. I do not think extraction ought to be performed for this form of injury; because the pupil is so small, that, when the section of the cornea is completed, the lens jerks out with a degree of impetuosity which renders the risk of lacerating the iris very great. The iris, too, from its expanded condition and proximity to the cornea, is very apt to be wounded. Should the crystalline be fixed against the edge of the iris, it may either be placed in the anterior chamber by the operation of keratonyxis, or extracted. When the lens is forced into the anterior chamber by a fall, or other injury, it is generally softened and absorbed very rapidly. The treatment of this accident which I have found most beneficial, has been the following. General and local bleeding and purgative medicine, counter-irritation, and belladonna cerate to the eye-brow, on the first day of the accident; changing afterwards the purgative for calomel and opium. As soon as the hydrargyrus evidences its action upon the system, the inflammation is arrested and absorption quickened. The lens, however, may not be absorbed; and should it remain, and produce the symptoms enumerated in my last paper, its removal is not only justifiable but imperatively requisite. A lens so situated is most favourably circumstanced for the operation of extraction. I would again observe, that before this operation is undertaken, the acute symptoms ought to be subdued: it would be obviously improper to select the period of active inflammation for the performance of such an operation.

If the lens be dislocated into the anterior chamber, in consequence of chronic disease, the capsule yielding, from the extension of morbid action, to that part—if chronic inflammation of the iris and deep-seated textures be excited and maintained, by the rough and craggy surface of an ossified lens—if the capsule be wounded and the lens dislocated, by a fall or blow, in an eye previously affected with chronic iritis—or if, from any cause, a lens enlarged and indurated throughout its whole extent, be removed from its natural situation—the operation of extraction ought to be performed without delay, because there is no prospect of the removal of the lens by absorption. The inflammation will be augmented, and cannot be re-

moved whilst it (the lens) remains. There is no acute inflammation present, and by waiting, a more favourable opportunity for the performance of an operation will not be presented. The continuance of inflammation has rendered the surfaces with which the lens is in contact more sensible of its pressure; they are less capable of enduring its presence, without serious inconvenience, than when previously healthy. The opposite organ is very likely to participate in the irritation of its fellow, from having been kept for a long time in a state disposing it to suffer from a trivial cause.

The superiority of extraction, in such cases, over every other kind of operation, is very great: it excites little inflammation, removes the cataract altogether, and injures no deep-seated structure.

Birmingham, April 18, 1830.

A DUPLEX CHILD.

To the Editor of the London Medical Gazette.

SIR,

IF you think the following account of a case, which is very similar to that of the Siamese youths, worthy of insertion in your valuable journal, it is much at your service.

I am, sir,

Your constant reader

And well-wisher,

WM. MORGAN, M.R.C.S.L.

Carnarvon, 10th April, 1830.

A poor woman, the wife of W. Thomas, a quarryman, who resides near Llanberis, in this neighbourhood, was on the 28th ult. delivered of a duplex female child, still-born, which had two heads, two necks, four arms, two pelves, four thighs and legs, all perfectly and naturally formed. The two trunks were united at the breast bones, and the union extended as low as the umbilicus, where it terminated in one umbilicus common to both. Their union was so remarkably firm, that from the examination it appeared to me to be of bone; suffice it to say, that at their union I could not separate them the space of a line. From what I have already said, it must be evident that

their faces, and fore-parts of their bodies, were fronting each other. The midwife in attendance told me they were born with their arms around each others necks. From a careful external examination (for I am sorry to say I was not permitted to make any other), there appeared no reason why they should not have lived. It was evident they were of the full growth of the usual term of utero-gestation. The mother fancied they perished about a week before her accouchement. They measured in length seventeen inches and a half; I did not weigh them, but imagine them to have been about nine pounds. Their features much resembled each other, but the hair of the head of one was somewhat darker than that of the other.

[Cases of children united in a manner more or less similar to the above are not very uncommon. The following account of such an instance, in which the individuals lived, is taken from the Foreign Literary Gazette, for March 24, 1830.]

“Have you never heard of the twins that drew their breath at Szöny, near Komorn, in Hungary, anno 1701? These were two girls, who came into the world united below the spine; but otherwise forming two distinct beings, each having her own face, hands, arms, feet, &c. One went by the name of Helen, and the other by that of Judith, the former being the handsomest and finest moulded of the two. In the seventh year of their age they were sold to a physician, who gave them an opportunity of seeing Italy, France, Holland, and other countries, and at three years' end brought them back, with a booty of seventy thousand florins, (7000l. and upwards). When near their (or its?) tenth year, Augustus, the Cardinal Archbishop of Gran, placed them in the convent of Ursulines at Presburg, where they were instructed in religion, languages, lace-making, sewing, &c. They were much attached to each other, although a quarrel would occasionally spring up between them, when they would exchange fisty-cuffs, and the more robust, by way of cutting the contest short, would raise the weaker from the ground, and fairly march off with her. They could turn their heads on one side towards each other: Judith frequently slept whilst

Helen watched, or the one rested from her labour, whilst the other continued working; though it will be readily imagined, that whether they were sitting, lying down, or walking, either action was attended with much inconvenience to them. At the age of sixteen, Judith was struck with paralysis in her left side; it is true, she recovered, but her mind became duller, and her body far less active than before; Helen, in the meanwhile, continued as humorous, clever, and handsome, as ever. They had the small-pox and measles at the same time; but trivial indisposition, coughs, slight fevers, &c. would affect one of them, whilst the other enjoyed perfect health. Judith, in her twenty-second year, fell into a species of lethargy, and appeared to be dying; and Helen was simultaneously attacked by a slight fever, attended with faintings, which reduced her to such a state of debility, that scarcely three minutes before the decease of her sister, she was struggling for life; indeed, both expired nearly at the same instant, though in the perfect possession of their mental faculties.

"To this extraordinary and fully developed caprice of nature, I must add, that in March 1819, a Jewess, in the circle of Liptau, had twins with only one head, and in October 1813, a seven months' *monocephalos* was born, with two perfect faces at opposite sides of the head, the bodies being united in one, though it had double limbs and extremities. Such a *lusus naturæ* was probably the origin of the Roman Janus."

MEDICAL GAZETTE.

Saturday, April 24, 1830.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."—CICERO.

INTENDED PUBLIC DINNER.

It is intended that a public dinner shall take place on the first of next month, for the purpose of commemorating the decision of Lord Tenterden in the cause *Handey versus Henson*, by

which the general practitioner is recognised in his *professional* character. Of the importance of that decision to the public, and to every department of the medical profession, as well as to the class of practitioners more immediately interested, we have already spoken. We have declared it to be, in our humble judgment, an event calculated to induce a reform—"not such as disappointed and half frantic demagogues have raved about till the very word became a scorn—but a real and substantial reformation, honourable to the profession, advantageous to the public, and beneficial to science." Let these, which were our earliest expressions on the subject (see *Gazette*, Jan. 23), be the triumphant answer to those who would insinuate that we are hostile to the measure, or undervalue its importance, because we differ from them as to the best means of turning it to account. It is undoubtedly true that we have been opposed to the plan of celebrating this event by a dinner, and we shall explain our reasons for being so. We object to it, first, as not calculated to effect the end in view; and, secondly, we have objected to it as calculated to give the appearance of a connexion between the general practitioners and those who are justly regarded as constituting the least reputable part of our profession—a connexion which we deny to exist.

As to whether the celebration of this decision by a public dinner be likely to benefit the interests of the general practitioner, there may be, and obviously are, differences of opinion; but we have never heard any rational explanation of the advantages which are expected to result from it. It cannot be intended to make the circumstances of the case better known to the profession, for there are probably not ten practitioners in the empire who are not already fully aware of it. The decision has been mentioned in terms of commendation in

all the medical journals, of whatever political creed;—how much soever they may differ on other points, here at least all have agreed. Is the dinner, then, intended to direct the attention of *the public* to the merits of the question? Such will be its effect, whether it be the intention of those concerned or not; and it is this which, in our opinion, renders the proceeding so injudicious. The public know only that an apothecary brought an action against a patient, in order to obtain a sum of money for his attendance, as well as for his medicines, and that he succeeded in his suit. They know that the “victory” has been “shouted forth in terms hyperbolical” by a certain portion of the press, and they now see that a public dinner is to be held to celebrate the event as a triumph—over themselves. Gentlemen may talk about the decision being an advantage to the public as great, or greater, than it is to *them*—we know it; but the public do not, and will not, view it in this light, till by experience they have come to feel it as such—and the change would be much more beneficially effected by general practitioners gradually substituting charges for attendance instead of for medicine, wherever they find that they can do so with safety to themselves—rather than by a flourish of trumpets, and thus attempting to carry the measure into effect by a *coup de main*.

We remember, some years ago, the practitioners in a particular neighbourhood, thinking themselves generally underpaid, held a public meeting, and agreed to a certain rate of remuneration which they were to demand. Strong in the justice of the case and fairness of their intentions, they published the document, and circulated it among their patients. Now the consequence was, that they were nearly ruined; for there were some practitioners within reach who had not attended the meeting, and they con-

tinuing to visit on the former terms, the whole scheme, which, in their tavern orations, and in their toasts after dinner, appeared so promising—ended in smoke. Now, unless great circumspection be used on this occasion, something of a similar kind may be apprehended. Those who attend the meeting may expose themselves to the imputation of being the “doctors who charge for their attendance as well as their medicine;” a result which could scarcely be beneficial to their interests.

It is a most important crisis, and a false step may be of infinite mischief. Such, at least, is our view of the matter, and which we, therefore, think it our duty to offer—*valent quantum*.

But further: we have also said that some of those most anxious to promote this dinner were connected with the least reputable part of the profession. An anonymous writer (see Gazette, March 27th) is very angry at this, and says it is not true. But facts are stubborn things. We happen to know that a set of papers, requesting the signatures of those interested in these measures, and willing to contribute towards some method of making them more public, were sent from the LANCET office to some of the principal medical booksellers; and we also know that an attempt was made to have the name of LAMBERT inserted in the list of stewards. When, with these circumstances, we consider the abortive efforts made last year, by Wakley and his friends, to get up a dinner, and observe the tone assumed in the Lancet on this occasion, we feel fully warranted in asserting that the same party was extremely anxious to be mixed up with the present proceedings, and thus to identify its interests with those of the general practitioner. This was so apparent, that many respectable men, abundantly friendly to the general cause, held back, from a conviction that no good could come from such a source; and the dinner,

after being advertised repeatedly, was postponed, and had nearly been altogether abandoned. The few who had favoured the objectionable measures above alluded to, having become convinced, by this unequivocal demonstration of public opinion, of the absolute necessity of avoiding all party questions, if the public dinner was to be carried into effect at all, and some highly respectable gentlemen having consented to become stewards, there is now every prospect of the measure being accomplished. Such being the case—though we cannot change our opinion as to its expediency—we sincerely hope it may answer the purpose intended by those gentlemen who view it in a different light, and for this purpose the stewards ought to put Mr. Hume up to the peculiarity of the circumstances, and to take care that, in the event of any improper characters intruding, no blockhead be allowed to disturb the meeting by proposing toasts, or otherwise exciting party spirit, on an occasion where it is essential to the interests of all that the proceedings shall wear, in the public eye, the utmost appearance of cordiality, moderation, and gentlemanly feeling.

EXTRACTS FROM JOURNALS,

Foreign and Domestic.

NEW MEDICINAL SUBSTANCE.

THIS substance has been obtained by MM. Caventou and François, from the foot of a Brazilian tree of the family of the rubiacies, called the *caïuca* (*chiococca racemosa*,) and in Bahia by the name of the *rair-prela*, or black root. The peculiar chemical principle which gives character to the extract of this root, has tonic, without exciting, properties. It slightly purges, and is very diuretic. Its mode of action on the urinary passages is remarkable; the first day it very little augments the quantity of urine evacuated, but on continuing to administer it, the effect is progressively increased from day to day. As the augmentation of action is slow, no un-

due irritation is produced; and in consequence, the administration of this body as a medicine has never produced more favourable effects than in those cases where the urine, red and irritating, has been rendered with much pain.

The extract of the root being tonic, purgative, and diuretic, it is evidently applicable in cases of dropsy, and very favourable results have been obtained in several instances of this kind.—*Bull. Univ. C.* xix. 333.

EFFICACY OF OPIATE ENEMATA IN DELIRIUM FROM WOUNDS, &c.

Delirium without fever, or cerebral alteration, is a frequent consequence of great operations, wounds, &c. It is characterized by an extraordinary loquacity, complete incoherence, and continual movements, which are not prevented by the pain that naturally accompanies the lesion under which the patient may labour. Thus those having comminuted fractures of the lower extremities have been known to tear off the bandages, and to walk on the broken limb, without testifying the least pain; and others who had been operated upon for hernia, to thrust their fingers into the wound, and amuse themselves with pulling out their bowels, just as if they were doing so on a dead body. This state of exaltation of the nervous system may lead to the most unpleasant or fatal consequences, if not combated by proper remedies. The treatment which M. Dupuytren has found most efficient, is an opiate injection. A purgative enema is first thrown up, to empty the large intestines; after which the narcotic is administered. Fifteen or twenty drops of liquid laudanum are in general sufficient. But it is very important in the use of this remedy, that it should remain three or four hours in the rectum. Under these circumstances, the moderate dose above-mentioned is sufficient; whereas much larger quantities of laudanum, if they have been speedily ejected again, have been of no service. M. Dupuytren is of opinion, not only that fifteen or twenty drops are sufficient, but that, in these cases, the medicine acts more beneficially in the form of clyster than when taken by the mouth.—*Journal Hebdomadaire.*

AN ACCOUNT OF THE GIRAFFE, WHICH LATELY DIED AT SAND-PIT GATE.

By Mr. W. J. GOODWIN, V. S. to the King.

The attention of British naturalists

has of late been particularly directed to the giraffe, from the recent death of one of these animals in the King's menagerie. It was brought to England in August 1827, and was then about a year and a half old, and it died at Sandpit gate in October 1829.

It was evident, on its first arrival, that there was considerable disease in several of its joints. The knee, the fetlock and the hock, were swollen and distorted, and the peculiar gait of the animal was more than usually awkward. Inflammation had plainly attacked the synovial membrane of these joints, the cause of which had doubtless commenced while the poor beast was fettered and bound on a camel's back, being too young to travel. The journey overland was, however, performed by the giraffe now in Paris without injury, for it was a twelvemonth older than that which was presented to his Majesty.

This disease of the joints continued to increase in spite of the most careful treatment, and, at length, rendered every movement of the animal exceedingly painful. For several months before it died the limbs became powerless; and it was requisite to support it in the erect position by a sling, to the use of which it became perfectly reconciled.

The inflammation proceeded to ulceration of the synovial membrane and cartilages, and which extended deeply into the bones of several of the larger joints; and this interesting animal died worn out with pain, the excruciating nature of which was sufficiently obvious on the post-mortem examination of the joints.

The giraffe belongs to the class *mammalia*, and the order *ruminantia*: it bears some resemblance to many species of this order, but it is distinguished from all of them by several striking peculiarities. It resembles the camel in the length of the neck; in the callous substances found on the breast and knees; in the construction of the feet, which have no false or supplementary hoofs; and in the height of its stature. This resemblance had been noticed by the Romans, by whom it was called the *camelopardalis*, the camel spotted like a pard.

It, however, resembles still more some of the species of *deer*, in the apparent rudiments of horns, covered by the integuments, hairy, and crowned with a tuft of bristles, which may al-

most be fancied to be the development of the horns; in the general shape and character of the head; and in the large soft eye with elongated pupil. The eye of the poor animal that died at Sandpit was the admiration of every one, and its countenance truly indicated its gentle and inoffensive character. The general form of the body, the obliquity of the back, and the slenderness of the legs, remind us of some of the deer tribe. It has, however, characters not recognized in the camel or the deer. On the forehead is a large tuberculous projection of bone, lengthened towards the nose, and the nasal bones are singularly prolonged, almost to deformity. The muzzle and lips are those of the horse, rather than the camel or deer: the principal peculiarities of its conformation are the length of its forelegs, the elevation of its withers, and the extent of its neck, which are out of all proportion to the other parts. Some are said to have been no less than twenty feet high, from the crown of the head to the sole. The larger one in the British Museum measures seventeen feet in height. His Majesty's was not more than twelve feet high; but it was young when brought into this country, its growth was stunted by constant disease, and the distortion of its limbs materially lessened its apparent stature.

The natural motion of the giraffe is a kind of amble, with the neck extended, and the animal, as may be imagined from his form, is far from being swift. Progression depends chiefly on the hinder quarters, which are singularly short and deficient in this animal. The nostril narrow, compared with the bulk of the animal, and the lengthened windpipe, are incompatible with speed.

The natural food of the animal is pointed out by his form. Although the neck is of great length, the height of the fore-quarters prevents the possibility of his reaching the ground with his muzzle, and therefore he browses on the leaves and succulent branches of trees. The Sandpit giraffe was chiefly fed on barley, hay, and the shoots and branches of the acacia tree, and other species of the mimosa. It preferred almost every species of green food to that which was dry, and ate it with avidity. Its little appetite for water seemed to fit it for the arid country whence it came. It consumed about two quarts only daily. At times it would not drink

for a day or two, and afterwards would eagerly swallow a larger quantity.

The thoracic and abdominal viscera were carefully examined, and closely resembled those of the deer. The liver was rather small, divided into two principal lobes, and without a gall-bladder, but the biliary duct was very large. A description of the tongue and the stomachs, with accurate drawings, will be published by Sir Everard Home.

The length of the intestines was 156 feet, seventy of which were occupied by the colon, cæcum, and rectum: the two former had none of the longitudinal bands, puckering them into numerous cells, as in the horse, nor were they so capacious as in that animal; but the colon diminishing in size, and formed several circular convolutions on the left side of the abdomen.

The skin has been admirably preserved and stuffed by Mr. Gould, of the Zoological Society. The skeleton also is in a state of forwardness, and will be the only perfect one in this country. When completed I shall probably resume my description of this rare animal.—*Veterinarian*.

BUCCINA—NEW PRINCIPLE IN BOX-WOOD.

An apothecary of Bordeaux announced to the Pharmaceutical Society of Paris, at its last sitting, that he had discovered in the wood, and particularly in the bark, of the box-tree, an alkaline principle, to which he gives the name of *buccina*. It is in the form of powder, and neutralizes acids, forming uncrystallizable salts: it has a very strong sudorific action and bitter taste. M. Dupetit Thouars, in making this statement at the Philomathic Society, remarked, that *buccina* might perhaps be advantageously used in the manufacture of beer, "for there is more box-wood than hops employed in making almost all the beer brewed in Paris."—*N. M. Mag.* xxx. 112.

HOSPITAL REPORTS.

HOTEL DIEU.

Foreign Body in the Air-Passages— Tracheotomy—Observations.

A LITTLE girl, eight years of age, sent on a message by her mother, was

tempted by the appearance of a haricot-bean in a shop, and having stolen it, put it into her mouth for the purpose of concealment. This was done in a great hurry, and as she made a deep inspiration at the moment, the bean was carried into the larynx, and subsequently passed into the trachea, where it remained. Violent cough instantly came on, and was accompanied by a sense of impending suffocation. The accident happened on the 3d February. Several practitioners were called, and an emetic was prescribed: this produced copious vomiting, but without getting rid of the foreign body. The rest of the day was passed in alternations of fits of suffocation with intervals of quiet. On the 12th, M. Delens, under whose care she was, sent her to the Hotel Dieu. The night between the 12th and 13th was very restless, the fits of choking being very violent, and frequently followed by long-continued loss of consciousness, which led to serious apprehensions of her death. Next morning the cough was still very severe: on applying the ear on the windpipe, a peculiar noise was heard, and the *shock* of the foreign body perceived on breathing.

The necessity of removing the bean was obvious, and M. Dupuytren determined on performing tracheotomy. This was done accordingly on the 13th (February), in the following manner:—A few moments before commencing the operation, the shock of the foreign body against the parietes of the air-tube was felt for, but it was scarcely to be perceived just at this time,—a point to which we shall return. The child placed on a bed, and held by assistants, the head being thrown back, an incision was made about an inch and a quarter in length on the median line, and a little above the upper end of the sternum. At first the skin only was divided, then the subcutaneous cellular tissue—this last being done with great precaution: arrived at the muscles, these were separated, and the trachea in this manner was reached without any vessel, arterial or venous, having been divided. M. Dupuytren then, by means of a straight and sharp bistoury, guided by the nail of the fore finger of the left hand, divided vertically several rings of the windpipe, with their connecting membrane. At first no air made its escape, nor was the voice at all altered, which

much surprised the operator and his assistants; but the incision being a little extended at both extremities, and held apart with the point of a forceps, air issued from the opening. The head of the child being now moderately flexed, the air was expelled with greater force, and after some violent efforts at expiration, the bean, covered with bloody mucus, was ejected, and fell on the child's breast. The respiration then returned to its natural state, the cough and suffocation ceased, and the little patient appeared to be well. The edges of the wound were carefully wiped, so as to remove all the blood which covered them. They were not brought together, but a simple compress of linen, pierced with holes, and spread with cerate, was laid on the front of the neck: no charpie was used. A bandage of very moderate tightness kept the dressing in its place. The haricot was more than five lines in length, three in breadth, and as much in thickness. It was a little swelled.

In the evening there was a smart attack of fever, for which she was bled. The night was pretty good.

14th.—The air passes freely by the wound, and respiration seems to be almost entirely performed through the adventitious opening. There is some pain in the larynx, with occasional fits of difficult breathing. Fifteen leeches to the throat; diluent drinks. The leeches bled freely, and produced permanent relief. The cough became less frequent, and there was little fever.

15th, 16th, 17th.—Respiration free; a little hissing is heard at the wound, by which the air now only issues in small quantity. Voice natural.

20th.—The edges of the wound have been approximated, there being no longer any danger of emphysema.

From this time no accident of any kind occurred to the little patient. In a few days more she was removed by her parents, who brought her back a month after to shew the state of the wound. There was then only a very minute aperture left, and as it was gradually diminishing, it was expected that it would soon close entirely.

Observations.—The above case offers several interesting considerations:—

1st, With regard to the position in which the child was placed in order to

divide the external parts and trachea most favourably, and then with regard to that afterwards assumed to admit of the exit of the foreign body. For the former purpose the throwing back of the head is very convenient, and renders the first steps of the operation very simple; but for the escape of air, and, *à fortiori*, for giving exit to the foreign body, it is unfavourable. And in fact, it will be observed, that the incision first made in the trachea did not suffice for either purpose. This, perhaps, was partly owing to the smallness of its size, but it was also in part dependent on the posture; for the extension of the head stretches the borders of such a wound, and thus keeps them from separating. But when the head is bent forwards, the reverse of this happens, and it was during this latter period that the foreign body was thrown out. From this it follows as a useful maxim in such cases, to have the head extended in making the incisions, and flexed afterwards to open the wound. There is another point to which it may be useful to allude. There exists between the sterno-thyroidei and sterno-hyoidei muscles and the anterior part of the trachea a space filled with cellular tissue, which is loose, and forms a kind of cavity. When the instrument arrives here, if it does not penetrate at once into the windpipe, it may be thrown into a wrong direction in this cavity, and lead to difficulty. Being aware of the circumstance, this is easily guarded against by a little attention.

2d, We would direct attention to one of the signs characteristic of a foreign body in the windpipe; namely, the shock it communicates to that tube: this is a sensation which can be perceived by the ear, or even felt by the hand. It is not, however, always equally distinct in different individuals, nor indeed at all times in the same case. In fact, the body may become adherent, and consequently it may not be impinged, by the act of breathing, against the windpipe, or else being enveloped in an abundance of thick mucus, the shock it produces may be too slight to be perceived. Accordingly, we have seen that in the above case, although distinct at the time of the patient's admission, it was much less so when the operation came to be performed. This sign was particularly pointed out by M. Dupuytren, and we

have not noticed it in any other author. It may obviously be useful in the diagnosis of obscure cases.

3d, The mode of dressing which was adopted also deserves attention. The edges of the wound were not at first approximated, for fear of bringing on emphysema. At first the cellular tissue would have been permeable, and would probably have afforded a ready passage to the air. But at the end of some days, glued by the inflammation, and rendered compact, this was no longer possible, so that the healing of the wound could with safety be hastened by the approximation of its edges. The propriety of this practice is too obvious to require that we should enlarge upon it. We may also remark, that no charpie was employed; experience has shewn that it sometimes finds its way into the trachea, giving rise to very troublesome effects.

Foreign Body at the upper part of the Larynx—Extraction.

A woman, aged from 45 to 50, presented herself for consultation at the Hotel Dieu on the 30th of March, requiring assistance for an accident which had happened to her eight or ten days before. In eating some fish she had swallowed a bone, and immediately afterwards was seized with pain in the neck, and in the situation of the upper part of the larynx;—this continued, and was felt not only in swallowing, but breathing. The pain, which at first was only inconvenient, became more and more acute, and it was to get cured of this that she came to the Hotel Dieu. The patient having the mouth widely opened, and submitting in other respects extremely well to the necessary manipulations, M. Dupuytren introduced his finger along the base of the tongue to the epiglottis, which he particularly examined all round. He felt, near its base and at the outer edge, a projection about the size of the head of a large pin; the rest of the body, the nature of which he could not determine, but which, from the account of the patient, he suspected to be a fish-bone, was situated within the epiglottis. M. Dupuytren having the fore finger of one hand resting on the projection made by the foreign body, introduced along it a forceps, with which he seized the projecting part.

Certain that he had hold of it, as the handles of the instrument did not touch when they were brought together, he pulled gently, and drew out a fish-bone an inch and a quarter in length. This was effected with little pain and no bleeding, and probably the patient experienced no further inconvenience, as she did not return to the hospital for further advice.

This fact is only one of many others of the introduction and detention of foreign bodies in the air passages; but it is remarkable, in so far as the bone was fixed in the sides of the larynx and across its upper extremity. It is also curious, that the irritation, in general so violent when foreign bodies find their way into the air passages, was here so inconsiderable that the patient was but little incommoded for eight or ten days. It illustrates the extreme difference in the sensibility of the same organs in different individuals.

EDINBURGH ROYAL INFIRMARY.

Necrosis of Femur—Amputation—Secondary Hæmorrhage—Ligature of the Common Iliac Artery.

ROBERT PEDDIE, æt. 8, admitted under the care of Mr. Liston, Nov 6th.

There is considerable swelling of the right thigh, extending from the trochanter major to the knee, arising from enlargement of the femur, which is increased in size chiefly towards its lower extremity. About four inches above the knee there are two fistulous openings, one on the outside, the other on the inner side of the limb. A probe was introduced obliquely upwards from each of the apertures for upwards of two inches, and a large portion of the bone was found denuded, but no loose portion could be felt. The affected limb appears a little elongated, with slight flattening of the hip; but the rotatory motions of the thigh are perfect, and performed without pain. The patient is considerably emaciated, has night sweats, and slight thirst, but a good appetite, and no diarrhœa. Pulse 112, and irregular; tongue clean and moist.

The swelling of the thigh occurred twelve months ago, after a severe fall on the ice. The opening formed some months previous to admission.

23d.—The limb was removed yesterday immediately below the trochanter minor, by the anterior and posterior flap operation,

Mr. Liston having previously satisfied himself that the hip-joint was free of disease. The bone, where sawn, was considerably thickened, but otherwise free of disease. Ten arteries were secured, and the flaps retained by interrupted suture.

Mr. Liston's prognosis was rather favourable, and he was of opinion that the remaining bone, being merely enlarged, would soon diminish in size after the removal of the irritating cause.

On exposing the diseased bone, it was found very much enlarged by the deposition of new osseous matter, and a large external sequestrum was situated on its posterior surface, detached at its upper extremity, but firmly fixed towards the knee. The periosteum was thickened and vascular, and the surrounding parts were of semicartilaginous consistence.

Soon after the patient had been put to bed, he was seized with violent vomiting; anodyne draughts and solid opium were administered, but were speedily ejected; brandy was given frequently, and in small quantities, and had the effect of in some degree abating the violence of the vomiting.

24th.—Passed a restless night, and the vomiting occasionally recurred. Pulse rapid and weak; feet cold. A sinapism to be applied to the epigastrium, and wine to be administered.

26th.—The vomiting has almost subsided; pulse less rapid and more full; stump looking well; bowels regular.

27th.—The vomiting has entirely ceased. The patient has a cough, with considerable thirst, and complains of slight pain of the abdomen, somewhat increased by pressure; his bowels have been freely moved; stump discharging dark-colored matter; pulse 140, and of better strength; urine scanty and high colored; feet rather cold.

28th.—Has still cough, with slight pain of breast. A sinapism was applied to the chest, and an anodyne draught administered. Ordered ʒiij. of wine.

30th.—The cough is trifling, and he has no pain of breast; pulse 120, and of good strength; the stump looks well, and discharges a considerable quantity of healthy purulent matter; tongue moist; bowels open.

1st Dec.—Soon after the visit yesterday there was some oozing of blood from the stump, and during the afternoon it increased in quantity. The hæmorrhage was found to proceed from an ulcerated cavity of considerable size, opening towards the outer angle of the wound; a coagulum was removed with the finger, and the cavity stuffed with lint. The hæmorrhage was arrested at the time, but soon returned, became more profuse, and could not be stopped by the usual applications.

At 9 p.m. was visited by Mr. Liston, who

proceeded to secure the common iliac artery. He commenced the incision about an inch above the anterior superior spinous process of the ilium, and two inches towards the mesial line, and continued it for upwards of three inches to over the internal ring. The transversalis muscle and fascia were divided on the finger, and the peritoneum was carefully separated from its attachments from below upwards, and pulled gently upwards and towards the opposite side, by the hands of the assistant. The ligature was applied by means of a common aneurism needle, and the edges of the wound were brought together by a few points of suture.

Mr. Liston stated that he had felt it to be his duty to secure this large vessel, in consequence of the severity of the hæmorrhage, and the exhausted state of the patient, though the chances of recovery were but slight.

After having been put to bed, the patient remained composed for a considerable time; but violent vomiting afterwards occurred, and brandy and opium were again administered.

The vomiting still continues; he is restless, and complains of pain in the epigastrium, increased by pressure; pulse 150, of tolerable strength. A small sinapism has been applied to the epigastrium. Afterwards the vomiting became much less frequent, and the brandy was continued; but towards evening his pulse became weak, he lay in a state of stupor, talked incoherently, occasionally screamed, and was affected with slight convulsive twitchings. At 7 p.m. the pulse was imperceptible. From five to six ounces of blood were transfused into the basilic vein of the right arm. After the operation of transfusion, the breathing became a little more hurried than previously, the skin was warmer, and the pulsation of the radial artery was quite distinct, and gradually became stronger, being about 140 in the minute.

He afterwards appeared to rally for about an hour, after which he again sunk, and died; about an hour and a half after the operation of transfusion, and upwards of 24 hours after the ligature of the common femoral artery.

On examining the body, the ligature was found applied to the common iliac, about half an inch above its bifurcation, and surrounded by a considerable quantity of effused lymph; there was a small coagulum above its constricted point. The extremity of the superficial femoral artery was quite imperious. The hip joint articulation was perfectly natural.

ST. THOMAS'S HOSPITAL.

Spontaneous (?) Gangrene of the Left Foot—Separation of the Foot by the Natural Process.

JOHN HERRIS, aged 32, admitted on the 25th of February into Henry's Ward, No. 1, under the care of Mr. Travers. The patient says, that about a week ago he was suddenly seized with a numbness of the whole of the left foot, which was soon followed by a discolouration of the skin, presenting a dark brown appearance. His occupation being that of a coal porter, and at this time being out of employment, and having an ulcer on the right leg, he was giving the limb rest when he perceived the above affection of the foot come on. It should be observed, however, that as soon as he found the numbness attack his foot, he immediately put it into warm water; and it was not until then that the discolouration showed itself. Having remained in this state for the space of a week, he was then taken to the City Workhouse at Stepney, where he had a cold lotion applied to the foot; this took place on a Tuesday, and on the following Thursday he was brought to this hospital. When we first saw him, which was not until the day after admission, the integuments of the left foot presented a livid black appearance, the discolouration extending about two inches above the ankle joint; vesicles, containing fluid, were here and there seen. No distinct line of demarcation, separating the living from the dead part, was yet discernible; the discolouration was insensibly lost in the adjacent living structure. He complained of slight pain in the ankle joint, and all sensibility below it was entirely absent. Pulse quick, with moderate power; tongue clean; bowels constipated. On the lower and inner side of the right leg he had a large, indolent, and unhealthy-looking ulcer, which he said first originated from a scald about six years ago. He was ordered to take a colocynth and calomel pill immediately, and house medicine occasionally; two grains of sulphate of quinine in infusion of roses three times a day; and half a pint of port wine daily, with a mutton chop: as a local application to the foot, equal parts of linseed oil and oil of turpentine; linseed meal poultice to the ulcer. Nothing different from the above state was observable, with the exception that the mortification did not continue to extend farther up the leg, until the 1st of March, when the line of circumvallation around the gangrene was perfectly formed, and the process of spontaneous amputation beautifully developed. It had a white appearance, consisting of raised cuticle, with a depression in the centre forming a groove, so that one half of the line was attached to the dead, whilst the other was devoted to the living side, with a slight blush of inflammation in the immediate neighbouring integu-

ments. The sensation in the part now became somewhat more acute; his tongue continued clean; bowels kept regular from house medicine; and general health good, being able to eat, drink, and sleep tolerably well. The same applications were continued as ordered at the first, until the 11th, when the oil and turpentine were omitted, and a lotion of chloride of lime substituted. The process of separation was going on favourably, and the patient in as good health as might be expected. On the 24th ultimo, he was directed to have the foot enveloped in a poultice, and instead of the chloride of lime wash, to have the part at the point of disunion wetted with a lotion of nitric acid, the strength of the solution being ten drops of the dilute acid to an ounce of water.

April 12th.—The foot had been for some time suspended only by the flexor tendons; and on the 10th it was entirely removed, and healthy granulations appeared on the stump. The leg was ordered to be strapped from the knee downwards, and other strips to cross the stump, and afterwards a roller applied.

He continues to do well.

Case of Otitis, with discharge, terminating in the formation of abscesses within the head.

Edgar Barton, 24 years of age, was admitted into William's ward on the 11th of December last with a swelling on the left side of the head, particularly above the ear. A sense of fluctuation could be perceived, but it was somewhat obscure; however a puncture was made, and a small quantity of matter evacuated, which was rather offensive; after which he expressed himself much relieved. A poultice was ordered to be applied to the part, and he took some of the saline mixture every six hours, with ten grains of the compound powder of ipecacuanha every night at bed time. This took place on the 13th; previous to which time no symptoms occurred except severe pain in the region of the swelling, and some discharge from the ear, which he said had not existed more than a fortnight altogether. On the evening following that on which the swelling was opened, he became restless, and during the night was delirious, in which state we found him the following day, so that it had been thought necessary to secure him to the bed with straps. His skin was hot and dry; tongue brown and furred; pulse upwards of 100, hard and full; and he was constantly endeavouring to remove the poultices. With respect to the chief seat of his pain, when questioned, he could not answer intelligibly, but pointed to the part that had been punctured. Fluctuation was now more evident, and an incision was made, through which there escaped about an ounce of offensive pus. Sixteen ounces of blood were taken from the arm; and a small artery being

divided on making the incision into the swelling, about three ounces of blood escaped from this source, when it was stopped by pressure. After the loss of blood he appeared to find relief almost immediately, and became more tranquil; still, however, remained delirious. Towards the evening the febrile symptoms had increased; his pulse was 120 and hard; bowels not yet open. He was then bled to ten ounces, and a dose of house physic administered to him. On the following morning he appeared less restless, but still remained unconscious of what was going on around him. There was no discharge from the wound, but a good deal from the ears. Bowels freely open. About three o'clock in the evening he was seized with a convulsive fit, which lasted upwards of a quarter of an hour; and was followed by another, of a similar nature, a little after 7. From this time he continued to sink rapidly, and between 9 and 10 he expired.

When his mother was examined as to his previous condition, she stated that he had been the subject of discharge from his ear from infancy, and within the last few years it had been constantly attended with a disagreeable smell. During this time he experienced considerable pain in his head; indeed so much so that at times he was quite frantic; and in addition to the discharge from the ear there was occasionally an escape of blood. Within the last fortnight he has scarcely ever been free from pain; and it was only at this time that they had first perceived the external swelling.

Inspectio Cadaveris.—On examination of the head externally, the periosteum was found denuded from the squamous plate of the temporal bone, nearly two inches in diameter, while the temporal muscle was in a sloughy state. On opening the cranium a circumscribed abscess was found between the dura mater and bone, corresponding to that which was situated externally: this contained upwards of half an ounce of unhealthy looking pus, having an offensive smell. The middle cerebral lobe corresponding to this was of a green colour, and softer than natural: when cut into, an abscess was found, about the size of a hen's egg, containing fetid pus. The posterior lobe on the opposite side was also cut into, and gave exit to a quantity of pus; and on continuing the examination after the brain had been hardened by alcohol and a horizontal section, made so as to expose the lateral ventricles, a communication was found between the abscess and neighbouring ventricle. On inspection of the ear, the meatus auditorius externus shewed long fungous granulations, arising from the membrana tympani; but a minute examination did not detect a communication between the external ear and the abscess between the dura mater and skull.

GUY'S HOSPITAL.

Large malignant Tumor of the Groin—Operation for its Removal.

CORNELIUS SULLIVAN, an Irish labourer of rather an unhealthy aspect, was admitted into the hospital on the 24th of February, with a large malignant tumor situated in the left groin. The patient states, that it first made its appearance about five years ago, at which time he received an injury of the great toe on that side from a blow; this produced a separation of the nail. Soon after the accident he perceived a swelling in the groin, but which was unattended with pain, and continued to be so until about two years since, when the pain was at times considerable. The tumor now presents an irregular appearance, bulging out at different parts, and is firm to the touch. When an indentation is made by pressure, it instantly springs up again. The integuments are smooth, and slightly livid, without ulceration. Two large arteries can be felt pulsating on the outer side, passing from the thigh to the tumor, and one on the inner side, proceeding from the pubes. It is intimately connected with the fascia covering the muscles on the upper and inner part of the thigh. On taking the measurement of the swelling, the girth of the substance was twenty-one inches; and around the pedicle, by which it was suspended, about fourteen inches; from this point, namely, where it was attached to the groin, to the opposite point underneath, crossing the tumor, sixteen inches. On lifting it up with the hand, the weight did not appear to be so great as might have been imagined from its dimensions. He did not complain of pain, except across the upper part, which is marked by a groove about two fingers width, passing from side to side, where it is also tender on pressure.

This case excited a good deal of interest among the pupils, as it was reported that the man had made application to several eminent surgeons, who refused to extirpate the tumor, on account of its being so closely connected with the parietes of the abdomen.—On questioning the patient at the time of admission, he stated that he had applied to different surgeons, who advised him to seek advice at this hospital.

On Tuesday the 2d of March the operation was performed for its removal by Mr. B. Cooper. The patient was placed upon the table, and the operator commenced by making his first incision on the left side of the tumor, beginning at the upper part, and carrying it round to the opposite point underneath the swelling. Although the incision was superficial, three arteries immediately began to bleed very freely, but were stopped by Sir Astley Cooper and Mr. Callaway making pressure on the mouths of the ves-

sels, and on the femoral artery, where it passes over the bone. A similar incision was next effected on the opposite side, and the dissection of the tumor continued, so that it was removed in about five minutes. Considerable hæmorrhage followed each stroke of the knife, which was arrested as much as possible by the assistants making pressure with their fingers. Pressure was also kept up on the femoral vein, as a good deal of venous blood escaped during the operation. Immediately after the removal of the tumor eight vessels were secured, and the edges of the wound brought together by sutures and strips of adhesive plaister, and a compress and roller applied, so as to keep up slight pressure on the part; a roller was also applied round the thighs, to keep them in a state of adduction.

The morbid structure presented a medullary appearance, so soft and pulpy that the finger could be thrust into it with great ease. It weighed between six and seven pounds. On the day after the operation the patient complained of slight uneasiness in the wound, and of more considerable pain on the left side of the abdomen, which was increased by pressure; skin hot and dry; tongue moist and white, but not coated; pulse quick.

Ordered a grain and a half of calomel, and quarter of a grain of tartarized antimony, to be taken immediately; effervescent saline mixture every four hours.

4th.—Pain increased on the left side of the abdomen, with acute tenderness on pressure. Pulse 103, small, but not sharp or hard; skin hot, rather dry; has been restless during the night, with little sleep; does not complain of pain in the wound; tongue as yesterday; spirits depressed; says he is naturally of a timid habit. At times he feels sick, and rejects whatever is taken into his stomach immediately after; scrotum is a good deal swollen, and painful; bowels opened by means of castor oil: towards the evening he had a dose of calomel and opium.

5th.—Pulse 104, more ample, and inclined to jerking; less pain and tenderness in the abdomen, and free from pain in the wound; several motions yesterday; tongue somewhat coated, but moist; has slept a little during the night; skin hot and dry; complains of pain in the head, and the sickness at stomach continues; scrotum as yesterday; a linseed meal poultice is applied to it. Mr. Cooper now directed the roller and pledget of lint to be removed, but the strapping underneath these to be left as before.

Ordered a grain of calomel, half a grain of opium, and two grains of antimonial powder, every four hours; also an effervescent draught, with camphor mixture, and three minims of black drop in each dose.

6th.—The remainder of the dressing has been removed to-day. The wound looks quite healthy, and his countenance has improved.

Omit the pills and continue the effervescent draught; to have four ounces of wine daily with his low diet.

10th.—Some of the sutures were divided yesterday, and the remainder to-day; healthy granulations appear between the edges of the skin. On the 8th a sloughing commenced in the scrotum. Yesterday a poultice of bread and water was applied to the wound, and he took twenty-five drops of tincture of opium at night.

17th. Going on well; the sore on the scrotum much cleaner. His allowance of diet has been increased, consisting of fish and eggs, and he is now ordered some veal.

April 1st. The wound is quite cicatrized, except at one point, where the only remaining ligature comes out. The scrotum is quite well, and the patient's general health very good; appearance considerably improved.

PRIZE MEDAL OF THE HUNTERIAN SOCIETY.

LECTURES ON SURGERY,

Delivered at St. Bartholomew's Hospital,

BY WILLIAM LAWRENCE, F.R.S.

— *from 104*

LECTURE XXXIII.

Tumors continued—Encysted Tumors—Ganglions—Diseases of the Skin.

In the last lecture, gentlemen, I spoke to you of tumors without concluding the observations which I had to offer upon that subject. I described to you a kind of growth which seems to consist of something very analogous to the cellular substance—the common cellular tumor. I spoke to you also of the adipose or fatty tumor, and of a morbid growth, corresponding to the description which is given by Mr. Abernethy, of what he calls pancreatic sarcoma; and also of another, under the head of tuberculated sarcoma.

In the case of cancer and fungus hæmatodes, we frequently find that these growths occur in the cellular substance as original depositions or newly-formed parts, and under such circumstances they would correspond with the definition of a tumor which I gave you in my last lecture, that is, of a new production occurring in the interior of any particular organ or part of the body which constituted no portion of the original fabric. The fungoid tumors are classed by Mr. Abernethy under the head of medullary sarcoma. He has given them the name of medullary from the softness of texture by which they are characterized; and he mentions cancer under the head of carcinomatous sarcoma. Now I have already spoken of these under the head of *specific diseases*, and therefore there is no occasion again to revert to the subject under the present division.

You may meet with tumors which do not in point of structure exactly correspond with

any of the descriptions that I have pointed out to you. There is a great diversity observed in the structure of these morbid growths, and I do not know that the whole of them can be considered to be comprehended under the various species that I have spoken of; the truth, however, is, that the distinction of tumors, grounded on the anatomical structure, is more important pathologically than practically. Generally speaking, we cannot ascertain the precise anatomical structure of the tumor till it is removed from the body, so that the anatomical structure is in general no guide to the course we adopt in the treatment of the case. I may, however, say to you in general in respect to these fleshy tumors, or sarcomatous growths, that if a lump of that kind form in any part of the body, if it is increasing considerably, if it produce conspicuous deformity, if it is inconvenient to the person from any cause, you may remove it by the knife whatever its structure may be. It is of no great practical importance, therefore, to distinguish very accurately the precise species of the morbid growth according to the anatomical structure, when you can have in point of practice only one course to pursue in the treatment of the case.

Encysted Tumors.

I come then to speak to you next of what we call technically *encysted* tumors. Cysts, which are constituted of a kind of membranous bag, may form in any organ or other texture of the body. These cavities or cysts are filled with contents of different kinds, varying in consistence from a watery fluid to a thick kind of fat. I say they may form in any texture or in any organ of the body; I believe we can hardly say that any kind of structure is exempt from them, except it may be the cartilaginous: I do not know any examples of the existence of cysts in them. But the osseous structure is not exempt. Cysts are formed in bones, although you might have supposed that the hard structure of these or-

gans would effectually prevent the development of any thing like membranous cysts. There is a curious case related by Mr. Keate, in the tenth volume of the Medical and Chirurgical Transactions, where a number of watery cysts were formed between the two tables of the frontal bone, constituting a tumor, the growth of which attained considerable size, and which, at last, by its connexion with the neighbouring parts within the cavity of the skull, produced very unpleasant symptoms, so that it became necessary to take away a part of the external table of the skull, and remove these morbid growths. Considerable difficulty was experienced in getting rid of the disease, which seemed to extend in circumference in proportion as it was destroyed in the original part, but ultimately it was completely extirpated, and appeared to consist of thin membranous cysts containing water.

Now it is not my present purpose to describe to you generally cysts as they occur all over the body; my object is only to speak to you of encysted tumors, considered surgically. We have, in fact, nothing to do with the cysts of various kinds that may be developed in the internal organs of the body. The very existence of these is not known till after death, and therefore it is a matter of no practical consequence. The encysted tumors to which I wish to direct your attention, are those which form on the external surface of the body immediately under the skin, or at least in the integuments. These are swellings which, in popular language, are called *wens*, and which the French have designated by the term *loupe*: they consist of cysts forming in the integument, and seated generally immediately under the skin, and are consequently developed in the stratum of adipose substance which lies immediately under it; and very commonly you will find that the skin adheres firmly to the convexity of the cyst where it approaches to the surface of the body. The cysts themselves are various in point of thickness. There are thick and thin cysts; there are cysts which are soft and delicate in point of structure, and others that are firmer, approaching nearly to a cartilaginous texture. The interior of these cysts is very generally smooth, and in fact presents an appearance a good deal like that of cuticle. Here are some specimens [exhibiting them] of some of these cysts. This cyst is divided, and turned inside out, to show the smooth cuticular lining. Here we have a number of cysts all taken from one individual.

The cyst or bag sometimes adheres firmly to the part which surrounds it—sometimes is connected more loosely. Different names have been given to these cysts or encysted tumors, derived from the nature of the substance which they contain: thus you will find the technical division of them in the old

writers. To a certain description the name of *Meliceris* has been applied, the substance in these resembling honey in consistence and colour. *Atheroma* is a name given to another set, which contain a soft substance in appearance a good deal like pap or poultice. A very great proportion of these tumors contain fat, either pretty liquid or solid, and this is called *Steatoma*. These are the three principal descriptions of tumor, which the old writers, according to their contents, have called *meliceris*, *atheroma*, and *steatoma*.

The appellation *steatomatous*, which means fatty tumor, has been sometimes applied to solid parts of fatty structure: it is not always confined to a particular kind of encysted tumor or wen. We sometimes find described under that term an adipose tumor of a solid consistence. These, however, are not the whole; they do not constitute the whole of the particular sort of contents that we meet with in encysted tumors. You sometimes have a liquid matter considerably more fluid than the contents of the melicerous tumor. I lately removed a large encysted tumor from the back of the neck of a lady, and it contained fluid which in appearance was much like turbid porter, with some portions of a granulated substance floating in it. Sometimes encysted tumors contain hydatids, and in fact there is a considerable variety in point of consistence and nature in the contents of these bags. Sir Astley Cooper observed in examining some wens or encysted tumors, that on that part of the surface which is towards the skin, you commonly find a minute opening, a sort of prick or point, which when you come to examine it with a probe or pin, you find to be an aperture leading to the cavity of the cyst. If you insert the end of the probe or pin into the opening, you find that the contents of the cyst may be squeezed out. Hence, he concludes, that these *steatomatous* encysted tumors or wens are in fact sebaceous follicles enlarged. Now you commonly find a great number of sebaceous follicles about the nose and other parts of the face, and in particular individuals it will happen that the excretory ducts of these follicles become obstructed by the substance they contain, and at the surface you see generally a black colour exhibited. You can by pressing the integument in which this takes place, squeeze out a white substance, which common people call a worm or grub. The idea of Sir Astley Cooper is, that the excretory duct becomes obliterated, and then that the secretion going on, and the follicle enlarging, constitutes these cysts.

Now the contents of most cysts correspond in appearance with the fatty substance I have described, and the cysts themselves with follicles, while there is the appearance of an internal cuticular lining, as I have already mentioned: there is, therefore, an

analogy between these bags and the follicles in the integuments with which they are connected. We not uncommonly find a mixture of hair with the fatty substance, a number of short hairs sometimes adhering to the side of the cyst, and sometimes loosely contained in the interior with the mass of the fatty substance. There is, however, this distinction between the hairs contained in these cysts and those that grow naturally on the integument,—the former do not possess bulbs. If you draw a hair out of the eye-brow or head, you find that at the root there is a minute bulb, which is the point from which it grows; but in the hair which is contained in these encysted tumors, the roots have no bulbs. The interior of these cysts is not only capable of producing hair, but also horn. Though it is not a very common occurrence, yet it happens sometimes that one of these encysted tumors ulcerates on the surface, so as to expose the interior cavity; the cuticular lining thus exposed, becomes dry, and assumes nearly the nature and appearance of horn. Under the part that has thus become dry, a new cuticle is formed, which also becomes dry. Thus there is a succession of cuticular formations, each succeeding one projecting its predecessor forward, and in this way they gradually grow and rise above the level of the skin, and if they go on, a horny production of some inches in length ultimately takes place, not having the exact figure of a horn, but analogous in the nature of its composition, and much like it in hardness and semitransparency. There are instances in which this growth has attained more than the length of the finger.

We cannot say respecting encysted tumors in general that they are always enlarged sebaceous follicles, because in many instances they form a considerable depth under the skin, in situations where naturally there are no such follicles at all. It is not uncommon to have these encysted tumors occurring as congenital productions. I have seen many instances where it was said they were such, especially about the eye-brow. Now it is remarkable, that when they occur there they are usually found adhering firmly to the bone, and are covered by the muscles. Then, again, you may have encysted tumors distinctly formed deeper than the subcutaneous adipose tissue; and I have already intimated that you may have these encysted tumors in the interior of the body, and in these parts they cannot be accounted for on the supposition of being enlarged sebaceous follicles.

Ordinary encysted tumors generally assume a globular shape, as in this instance, [shewing a specimen,] not completely spherical, because they usually have a compressed appearance on one part.

As I have already intimated to you, they

occasionally appear to be congenital productions; they are found in certain situations, and persons who have not noticed their origin at all, have supposed that they have existed from birth. I remember an instance of a small tumor of this kind situated on the root of the nose of a boy; it had an external opening, and had given a great deal of trouble. The parents did not like the appearance of the tumor; for there was a strong smelling secretion produced by it, which continued notwithstanding the use of various means. When I examined it closely, I perceived a hair growing from the aperture. Upon inspecting it more minutely, I found it to be one of those cysts from which hair is produced. It was seated behind the ala of the nose, and I found it necessary to divide the integuments freely, and cut to the bone, as a part of the membrane from which the hair was produced, adhered to it. It was similar to one of these [pointing to a specimen] cuticular encysted tumors.

Not uncommonly you meet with a multiplicity of these tumors on the body; they are apt to form on the head and the scalp. Under such circumstances very frequently a great number is found in the same individual, from half a dozen to a dozen. These in the bottle [shewing them] were all taken from the head of one person, and one of them, you observe, has got hair growing from the cuticular lining.

These encysted tumors are not in general attended with pain or inconvenience; they increase in size very slowly, and sometimes they remain stationary. I may observe to you in speaking of congenital tumors, that they take place about the eye-brow, and that I know persons who have had them all their lives, in whom the tumors never got beyond a certain size: they remained stationary. Occasionally, however, they increase and become troublesome, in consequence of their bulk, and as they are situated immediately under the skin, they produce an elevation of this, which is irritated and fretted, perhaps, by the dress or movements of the body, and thus they become a source of uneasiness. Sometimes they increase to a considerable magnitude, though they by no means arrive at the large size which I have had occasion to describe in some of the other tumors that I have already mentioned. The tumor that I stated I had removed from the neck of a lady, was about the size of a large orange: that was one of the largest I ever met with; you will seldom see one that has proceeded to that magnitude.

If an encysted tumor is stationary in point of size, and if it produce no particular inconvenience to the individual, you had better leave it alone; there is no necessity for doing any thing to it. If, however, it is increasing, if it is troublesome, or if it produce conspicuous deformity, particularly in a fe-

male, then you must get rid of it, and the only effectual and safe way of doing this is by the use of the knife: you must extirpate the tumor. A palliative mode of treating these tumors is by opening the central aperture which I have already spoken of, and enlarging it by introducing a probe, and squeezing the contents out, after which they will again slowly accumulate. If, however, you want to get rid of it, the only really safe and effectual proceeding, as I have already mentioned, is excision.

Then, as to the mode of accomplishing this, one method consists of making an incision over the projecting part of the tumor, and dissecting off the integuments on each side, and removing the tumor without opening the cyst. This requires a pretty large opening of the skin, and the dissection is often rather a slow and tedious one. Sir Astley Cooper proposes a mode of proceeding in which the object may be accomplished more quickly, and with a smaller external division of the integument. He divides the tumor and the integument which covers it perpendicularly, so as to split it into two halves; then the contents of the tumor can be removed, and the cyst collapses. You take up one half of the cyst and drag it outwards with a forceps, and remove it by a few strokes of the knife, and then do the same with the other. In many instances the cellular connexion of the cyst with the surrounding parts is so loose, that when you lift it with the forceps, it will come away of itself, and you remove it without dissection. But in other instances it adheres closely both to the skin and the parts on which it is situated, and as it is more troublesome to dissect it away under such circumstances, I would advise you not to tare out the cyst with the forceps, but first make the necessary division with the knife;—if you lacerate the parts, more particularly if they are seated about the head, you run the risk of producing inflammation, that would be unpleasant subsequently. You may adopt either of these modes, but I think you will find that Sir Astley Cooper's is the shortest, and that you will get rid of the tumor with a smaller external incision in that way than in the other. I must observe it is necessary to pay attention to remove the *whole* of the cyst. If you leave a part of it behind, future inconvenience is produced, and sometimes it is necessary for the patient to submit to another operation. I had under my care lately a lady from the country, who had a small encysted tumor of this kind, which appeared to be congenital, removed from the middle and lower part of the frontal bone, just above the nose. Being in town, she consulted me on the subject; she said, that the removal of the tumor had been a painful operation, and that subsequently to this, the part had continued red and sore;

that it sometimes healed up, but that it again became painful and troublesome; that it swelled, and a thin matter escaped, from it for some time. This was at the space of about a year from the performance of the operation for the removal of the encysted tumor, and in fact when I saw her, I found it was open. There was an aperture in the scar, and there was an oozing of thin matter from it. I introduced a probe, perhaps half an inch. She was convinced in her own mind that some part of the "bag," as she called it, had been left behind, and I could only ascribe its present state to that circumstance. I told her it was necessary to make another cut, and see if that were the case. This was accordingly done, and I found a small portion of the bag, not more than half the size of the finger nail, had been left adhering to the frontal bone. It was one of those cysts that are connected with the bone, and where we must go close to the bone to remove it. When I got it out, I found it was one of those cysts which have hair growing from them; she said, she had looked at the bag which was taken out before, and she saw that it had several hairs in it. When this portion of the cyst was removed, the part healed speedily, and it remained perfectly well. It is an unfortunate thing to leave any portion of the cyst when an operation is performed, for, under such circumstances, the tumor will not subside. The lady merely submitted to the operation for the purpose of having a deformity removed, but thus her condition was rendered worse than before; in fact, the tumor in the first instance only presented that sort of appearance which, I suppose, a phrenologist would consider merely as a considerable development of the organ of individuality.

I have several times had occasion to remove some of these congenital encysted tumors above the eye-brow, and at the angle of the eye; and I wish to impress upon your minds, that you usually find them adhering to the bone, so that it is necessary to make a free incision through the skin and to dissect carefully down; and pray be sure that you actually remove the whole, to avoid unpleasant occurrences of the sort that I have mentioned.

Other modes of dealing with encysted tumors have been proposed, in order to avoid the pain of dissecting out a bag of this sort. Some have proposed to make an opening into the cyst, to squeeze out the contents, and then inject an irritating fluid, so as to excite inflammation in the cyst, with the idea of obliterating it in the same way as with regard to the tunica vaginalis in hydrocele. It has been proposed to open the cyst, to get rid of the contents, and then to rub the interior with caustic; or to pass a seton through the cyst, to produce inflammation of the sides,

and to cause a deposition of adhesive matter, by which the cavity might be consolidated. Now the truth is, these proposals proceed on a false analogy. The cysts of these tumors are not like the serous membrane of the testicle; you therefore cannot expect to accomplish the same process by injecting irritating fluids into them. But farther, these cysts do not bear irritation well. You excite inflammation, the inflammation extends to the cellular and adipose membranes that surround them, and is speedily extended to the neighbouring parts of the limb; and thus you get diffused inflammation of the cellular membrane—a very formidable occurrence. Sometimes the irritation of the cyst causes a fungoid growth to be produced in it, of a malignant kind; so that you run the risk of bringing the patient, by your operation, into a worse condition than he was before, and that, in many instances, merely to get rid of a deformity. I deem all these proposals objectionable—either the puncturing or injecting the cyst, or the irritation of the seton, or any thing of the kind. All these are calculated to produce inflammation in the cyst, and thus lead to serious consequences; and in my opinion they are radically and entirely objectionable. You have the choice of two things in encysted tumors—either to leave them alone and let them remain quiet, or to cut them out; you must do either the one or the other—you must not take a middle course.

The tumors which are called *ganglions* are a kind of encysted tumor. They consist of a fibrous cyst, lined by a smooth membrane, and contain a fluid nearly approaching to the synovia of the joints. They are found in the neighbourhood of the fibrous sheaths which surround the tendons of the extremities. They are most common about the wrist and the back of the hand. They are generally smooth tumors, on which the skin moves easily;—usually they have an elastic feel; they sometimes are partly moveable, but in general they are fixed at the base. They are indolent, they arise insensibly, give no pain, and usually are only of a small size. They are commonly found about as large as a pea; it is seldom that any go beyond the size of a nut, or at all events of a walnut. When you puncture these tumors, you find them generally distended with a clear viscid fluid, very much like the white of egg;—sometimes it is rather thicker, and more like jelly; sometimes it is thinner, with a number of white granular bodies, like boiled rice, or sage, swimming in it. Some of these tumors are rather larger than I have mentioned. You are aware that there is a kind of large, loose, synovial membrane surrounding the flexor tendons of the fingers, where they pass under the annular ligament of the wrist; now that may be the seat of a swelling of this kind. You then find the

swelling is sufficiently considerable to be apparent towards the wrist and the fore-arm, on the one side, and towards the palm of the hand on the other. The contents fluctuate on pressure; if you press on the palm of the hand, the contents pass towards the fore-arm, or *vice versa*, the middle of the tumor being situated under the annular ligament. Sometimes the sheaths of the tendons become the seat of ganglion; and, in fact, there is an enlargement of the theca, containing fluid, and occasioning a general swelling of the whole limb.

These ganglions often, like the encysted tumors, acquire a certain size, and do not increase farther nor give any trouble; occasionally, however, they are troublesome—they produce inconvenience in the moving of the tendons with which they are connected, so that if you move the fingers it excites pain. Persons sometimes become anxious to find out some mode of getting rid of them: now one mode is to burst them. You apply pressure, strike a blow, or squeeze them, so as to crack the cyst and disperse the fluid in the cellular membrane. When a ganglion is seated on a bone, you can generally break the membrane with the finger and thumb, and thus disperse the swelling, and often it will not occur again; or if the swelling is reproduced, you can repeat the same process. This is a safe, and where you can accomplish it, generally an effectual proceeding. Sometimes this fibrous cyst is so dense, so hard, that with all the force you can exert in that way you cannot break it. Pressure has been recommended, but in general it is not very effectual. The method of using it is to apply a piece of sheet-lead, and bind it over the tumor. When that is not sufficient, persons have been directed to use irritating fluids—such as oil of thyme (*oleum origani*)—but we cannot place much confidence in them. If you cannot break them in the way I have described, perhaps the next best course is to puncture them, and then apply pressure. Evacuate the contents, let the parts be kept quiet, and then apply pressure. When there is a large swelling of this kind, occupying the whole finger, you may do good by subjecting the whole part to pressure. You can there apply pressure more effectually than in a similar ganglion about the wrist. If there be a large ganglion of this kind, or when it is seated on the flexor tendons under the annular ligament, and if the motion of the flexor tendons be interrupted, you have merely to puncture the cyst, and then close the wound again, so as to exclude the air, and then apply pressure.

In the treatment of large ganglia, some of those means have been recommended which I have had occasion to mention to you in speaking of encysted tumors—that is, the passing of a seton through the swelling, or

the injection of irritating fluids after evacuating their contents. But I consider all these proceedings decidedly objectionable, for the same reason that I objected to their employment in encysted tumors; and perhaps the grounds of objection here are even stronger—that is, the chance of exciting inflammation is more considerable. I have seen, in some French works, accounts of cases of large ganglia, affecting the tendons of the hand, treated both by injection and by the employment of setons; and M. Cloquet, the author of a work on Anatomy, which is now being published, relates his having seen two cases where setons were used in ganglia of this kind, where the inflammation that arose from them was so considerable as to prove fatal. I have seen a reference to other instances of the same kind, where fatal effects have been produced in this way; so that it is necessary for you to proceed cautiously in dealing with swellings of this kind.

DISEASES OF THE SKIN.

The next subject which I propose to speak of to you, is *Diseases of the Skin*.

The skin is very abundantly supplied with blood-vessels and nerves, and is exposed to all the varieties of external influence capable of producing disease. Hence you will not be surprised at finding that the diseases of the skin are very numerous, and that a great part of them exhibit a pretty active inflammatory character, in consequence of the facility with which disease, when it commences, spreads by continuity over a considerable part of the skin. The influence of those affections which in themselves would not be very important, thus becomes of consequence, from their spreading over a large part of the surface and affecting a large portion of the body. In this way, diseases of the skin are capable of very considerably disturbing the economy generally, because they interfere with important functions that are carried on by the affected parts. The skin is one of the great excretories of the body—it is one of the organs through which matters are got rid of that are to be separated from the body. You therefore see the necessity of this emunctory being in a healthy state, and that any disease that occupies a considerable portion of it cannot fail to produce a serious impression on the animal economy generally.

There is a great sympathy between the skin and the digestive organs. The condition of these produces a great effect on the state of the skin—so that a number of the affections of the skin are directly traceable sympathetically to disorders which originate in the alimentary canal. This influence is reciprocal; for, on the other hand, the state of the skin is capable of seriously disturbing the condition of the digestive organs.

The inflammatory affections of the skin differ very considerably in their character and degree, and in the effects which they produce. Some shew themselves merely in a state of vascular turgescence and fulness, others produce effusion on the surface of the skin, and various other effects. Now, as the diseased affections of the skin are very numerous, it becomes of consequence that they should be distinguished by appropriate names, so that we may know the particular affections of which we speak and read. When we hear merely that a person has an eruption, it gives us very little idea as to what the nature of the affection is, and the remark is equally applicable to certain terms which designate, in a general way, the diseased appearances of the skin—such as blotch, pustule, scale, and scab;—these, when used without discrimination, convey very little definite or clear information respecting the disease. There is a term of this kind constantly employed by the French writers—*dartre*; equivalent to the English word *tetter*. The term has been employed so generally, that we are at a loss to know to what affections of the skin it is applied. We had no very clear idea of the nature or distinctions of cutaneous affections until the late Dr. Willan undertook the investigation of the subject. He paid a great deal of attention to the various affections of the skin, and introduced something like a regular order and plan of arranging and distributing them in particular classes and species. Dr. Willan died before he had completed his investigation of this important subject; which, however, was afterwards taken up by an intimate friend of his (Dr. Bateman);—and to these authors we are indebted for a rational description of the diseases of the skin, in which terms are employed in a definite sense; so that when we speak of scab, or pustule, or vesicle, we mean a something which is perfectly clear, defined, and ascertained; and thus the various species of disease are designated by appropriate terms. The understanding of this subject is more particularly facilitated by an illustrative set of plates, of a very useful kind, published by Dr. Bateman, in quarto, and well calculated to elucidate the subject. The arrangement proposed by Dr. Willan has been found so useful, that it has been adopted by the best French writers on the subject. There is in the French language a large work, published by a Frenchman (Alibert), who, I believe, is physician to the king of France, in which there is a great number of plates of an expensive kind, but in which the old names and old arrangement, or rather want of arrangement, are still observed. But there is a late writer (M. Rayer) who has written a *Treatise on Diseases of the Skin*, and who acknowledges that the arrangement of Dr. Willan is decidedly the best, and, in fact,

adopts it. The work of Rayer is entitled *Traité Théorique et Pratique des Maladies de la Peau*, and is, in my opinion, a very good one; the descriptions are very clear, and the causes and all parts of the subject are treated very well.

Those affections of the skin in which there is merely a vascular turgescence, a distention of the vessels, and consequently increased redness, are classed by Dr. Willan under the head of *Exanthemata*, or *Efflorescence*. In common language, the term *rash* would be applied to these diseases.

When the inflammation of the skin is attended with vesication, so that the cuticle is raised into large bladders, these are called *Bullæ*, and they constitute an entire order of cutaneous affections.

When the cuticle is raised into small vesicles, as in the itch, or herpes, it belongs to the order of *Vesiculæ*. In cases where the inflammation of the skin is attended with the formation of pustules, as in small-pox, cow-pox, impetigo, and some others, it forms the order *Pustulæ*.

The inflammation of the skin is sometimes of a less violent kind; and without producing either serous effusion, or vesicles, or pustules, it produces a peculiar state of cuticle, covering the part, which constitutes a scaly condition. Hence the order *Squamæ*, scales, or scaly diseases of the skin. Sometimes the inflammation is limited to a small point, and produces a great number of minute inflamed pimples, or *Papulæ*. These are the effects of a pretty active inflammation affecting the skin; and you observe that the names of the orders are derived from the degree to which the inflammation is carried, and the effect that is produced. *Exanthemata*, *bullæ*, *vesiculæ*, *pustulæ*, *squamæ*, *papulæ*—these are the names.

There are changes of structure which are of a more chronic character, either arising from chronic inflammation, or sometimes from those organic changes which are of a more serious kind,—they constitute the order of *Tuberculæ*: elephantiasis, for instance, lupus, cancer, and so forth. Then there are a number of states of the skin which cannot be referred to any of these causes. We have congenital affections, *nevi materni*, discolourations of the skin, things that can hardly be called diseases; and numerous other affections of the cuticular covering of the skin, such as warts, corns, and various affections of the nails.

This is the foundation of the arrangement which has been adopted by recent writers on the subject of diseases of the skin. You will find that while a certain number of heads, such as I have now mentioned, are laid down as constituting so many orders or classes of diseases, if you enumerate under these all the various species which can be distinguished from each other, a very considerable number

of diseases of the skin will be set before you, and the catalogue will appear a long one. Now you are not to believe that all the various forms of disease to which names can be given, are essentially different diseases. They are, in fact, merely forms of the same affection, *inflammation of the skin*. The essence of the disease is the same throughout, though there is a difference in the form. The cause that produces it, the circumstances that attend it, the state of the individual in whom it occurs, produce modifications in form, but there is no difference in the essential nature of the complaint. You are not to suppose that each of these names renders the disease in its nature distinct from all others. In truth, you find occasionally that one and the same disease will exhibit those different appearances that would seem to entitle it to be arranged under different orders. Erysipelas is sometimes a mere efflorescence or redness; in other instances it is attended with large vesicles or bullæ; or it may be attended with smaller vesicles, such as constitute vesiculæ. Small-pox and cow-pox consist in their first stage of elevations of the cuticle from lymph effused under it. But in the course of the affection these vesicles are converted into pustules. Sometimes two or more of these forms are assumed at the same time. Thus, in a venereal affection of the skin, you have a scaly and a tubercular eruption co-existing in the same individual.

You are to understand that the diseases of the skin, like others, do not conform to the distinctions of nosology. You do not find those lines of difference that you see in the writings of medical men; on the contrary, the various supposed affections are gradually shaded off and blended with each other; but at the same time this regular arrangement and nomenclature is of advantage, because it supplies us with a language that we can use, so that when we hear of particular forms of disease we know what is meant by the terms employed. Before this arrangement was adopted in cutaneous diseases, we could understand very little of what was meant by a number of statements in reference to diseases of the skin.

LECTURE XXXIV.

Recapitulation.—Diseases of the Skin—Roseola—Erythema—Erysipelas.

IN the last lecture, gentlemen, I spoke to you of encysted tumors; and in mentioning the opinion entertained by Sir Astley Cooper, that they consist of enlarged sebaceous follicles, I stated some circumstances which tend to shew the analogy in point of structure between these productions and the integuments. I observed to you, that the fatty substance which fills these bags is similar to that of

the adipose membrane in which they are imbedded; I mentioned to you the cuticular lining which we find on their internal surface; and I observed to you farther, that they frequently contained, intermixed with the fat, growths of hair. Mr. Langstaff has been kind enough to favour me with a few specimens from his valuable collection, illustrating this subject.

I now shew you two specimens from animals. This is from a bullock; and Mr. Langstaff informs me, that where the colour of the hair of the animal is dark, the cuticular lining of the cyst is also dark: in this case both are dark. This is a similar tumor from a sheep, where the cyst contains a quantity of wool. This is a very capital specimen from the human subject, of a cyst turned inside out, shewing a large quantity of hair in it. You observe that the cyst is thickly covered by a hairy growth; and Mr. Langstaff confirms the fact which I mentioned to you, of these hairs being without bulbs.

I should have stated to you in my last lecture, but I omitted to do so, that the cysts sometimes contain hydatids; but those that do so are seated more deeply under the surface than those which are immediately cuticular, which lie in the adipose stratum immediately under the skin, and which contain the various materials that I described to you in my last lecture, more particularly substances of a more or less fatty nature. But sometimes we find that these encysted tumors are placed more deeply—perhaps under the superficial muscles, and these occasionally contain a large quantity of hydatids—that is, of globular cysts filled with animalcula, and adherent to the bag in which they are contained. Now I remember seeing an operation performed on a young woman who had a tumor on the neck, and we supposed that it might be a solid tumor; but when the integument was divided, and the part cut down upon, it turned out to be a large hydatid. There was a smooth cyst, and a large hydatid in it, which was taken out. I remember an instance of an operation in this hospital, where a tumor was removed from the fleshy part of the thigh of a female. It was rather deeply seated, so that no very clear opinion could be formed as to the composition of the tumor before the operation; but when it was exposed, it turned out to be a bag, containing a collection of hydatids. I met with an instance of a large cyst of hydatids contained in the orbit of the eye; and I may mention to you generally, that the loose cellular and adipose tissues in the intervals between the globe and the orbit, and the various muscles of those parts, are the seat of numerous growths, both of the sarcomatous and encysted kinds. The patient to whom I allude had a painful affection of the eye, or rather in the parts situ-

ated behind the eye. Gradually the eye began to protrude from the socket. The patient had very great pain deep seated in the orbit, and pain in the brow and neighbouring bones. The protrusion of the eye increased, vision became disturbed, and, in fact, at length was entirely lost. The pain in the eye and neighbouring parts increased, and became so considerable as to deprive the patient of rest, and render him very ill; he lost flesh, and seemed to be in a very bad way. These changes went on slowly; and on examining the case carefully, I found a prominence between the upper eyelid and the globe of the eye, and something that I could recognize as a distinct tumor. The extent of the tumor was uncertain, its boundaries by no means well defined, and it was altogether doubtful what to do in such a case; but after repeated examinations, it appeared that there was an obscure fluctuation in the tumor. From this circumstance I was led to puncture it, to see if it contained a fluid, and to get some kind of insight into its composition. When I punctured it a small quantity of perfectly transparent fluid escaped, and I did not know much more about the case than before. However, on seeing the patient a few days after, a sort of white membranous substance protruded at the opening, and I took hold of it with the forceps and drew out an hydatid. In the course of a few days, seeing the patient again, I drew out another hydatid, and some others followed. I was led to conceive from this circumstance that there might be a large quantity of these hydatids within the orbit, which had produced the swelling, and caused the protrusion of the eye from the socket; I therefore injected water into the opening I had made, and dislodged nearly half a tea-cupful of hydatids of various sizes, from that of the head of a pin to that of a large horse-bean, or larger. When the cyst was thus cleared of its contents, the eye passed back to its situation in the orbit. I did not know exactly what might happen with regard to the part in which this production of hydatids had occurred; however, inflammation took place in the cyst—purulent discharge followed—it then gradually diminished—the aperture closed, and the patient was completely relieved, so far as the existence of the tumor and the protrusion of the eye were concerned; but the protrusion of the eye had been too considerable, and the loss of sight had existed too long, to allow of the return of vision. I may mention to you generally, that tumors are frequently seen in the orbit; I have sometimes seen them containing watery fluid, and sometimes a fatty substance. With respect to these I may repeat what I said to you respecting encysted tumors occurring in other parts of the body: when by their bulk, or from any other circumstance, they interfere with the

functions of important parts in which they are seated, it becomes necessary to remove them. Now the necessity of removing them from these causes occurs more commonly when they are developed in the orbit of the eye than when they happen in other parts, because here there is but a limited space for them to grow in; and a small tumor soon interferes with the vision, and by pressing on the optic nerve and protruding the eye, produces an effect of such a kind, that you are compelled to take some measures for its removal at an early period.

I mentioned to you generally, in my last lecture, the divisions which had been adopted by more recent writers on the diseases of the skin; and I now proceed to offer such observations as I have to make on this subject.

In the first division of cutaneous diseases—that is, *exanthemata*, we observe simply vascular excitement, and distention of the blood vessels, and increased redness of the skin, in consequence of that distention; and in other instances these affections terminate either in the sudden disappearance of the symptoms—that kind of termination which I mentioned to you under the French name, *delitescence*—or in a little effusion or resolution, or very commonly by the separation of the cuticle from the inflamed skin—*desquamation*. In the case of measles and scarlet fever, this vascular excitement is general; it extends over the whole of the body, and it is preceded in these cases by a general febrile disturbance of the system, more or less severe, of which the cutaneous disease seems to be a sympathetic effect or symptom. The most important part of the affection in these cases is the febrile disturbance of the animal economy. People do not suffer in such instances from the derangement, so far as it affects the skin merely. These, however, are affections the management of which belong to the physician, and I have therefore nothing more to say of them at present.

Roseola and Erythema.

Under the head of roseola and erythema, pathologists speak of superficial inflammation of the skin, generally affecting a part only—that is, usually occurring in patches, in portions of greater or less extent, not accompanied with swelling, vesication, or any other change of that kind;—occurring either as the immediate effect of some external irritation, or more indirectly as the consequence of some internal affection.

In the work of Dr. Bateman, which I mentioned in my last lecture, there are some representations of these affections. These are two views [exhibiting them] of such efflorescence or redness of the skin, in patches of different forms or appearances, occurring in children, under the name *Roseola*; several species are given. There also are repre-

sentations of two other varieties of this kind of affection, *roseola variolosa* and *vaccina*—that is, superficial redness of the skin, occurring in conjunction with small-pox and cow-pox.

The name *Erythema* means simply redness, and the affection to which the term is given consists simply of increased vascular excitement in certain parts of the skin: there is no other change. When any external irritation is applied to the skin, such redness may be produced. The friction of the dress when it is too tight, will produce redness; the friction of folds of the skin in fat individuals, what is commonly called chafing, produces superficial redness and inflammation of the skin; and the application of heat, or any acrimonious substance, to the skin, will produce the same effect. Acrimonious discharges, as in the cases of gonorrhœa, diarrhœa, and dysentery, produce redness and various effects on the skin, in such parts as they come in contact with. In females affected with gonorrhœa, we see severe symptoms produced simply from the irritating nature of the discharge from the vagina upon the sound surface of the contiguous parts. We sometimes find the integuments of the parts over which the discharge flows, of a very bright red colour. If this continue we find the cuticle separate, and the parts become what we technically term *excoriated*—that is, deprived of the cuticle covering them. The inflammation which is excited in the skin loosens the attachment of the cuticle, which separates; and when this takes place there is generally a thin kind of discharge, usually of an unpleasant odour, taking place. While the cause continues, we find the inflamed surface will go into a state of superficial ulceration; and we find that warty excrescences will arise from them, and occasionally *condylomata*, which are flattened productions. All excrescences like these are simply the effects of some irritation of the skin.

Under the head *erythema nodosum*, Drs. Willan and Bateman have mentioned affections which consist of small patches of redness of the skin, particularly on the extremities, more especially the lower ones, in which there is not merely redness of skin, but a degree of inflammation and swelling of the subjacent cellular membrane. There is a figure of this affection in the work of Dr. Bateman, which is really very much like what we see in *erythema nodosum* [exhibiting it.] The patches are generally of an oval form, of a red colour, and more or less swelled; and when it becomes inflamed, it involves not merely the skin, but the subcutaneous cellular membrane.

Now the truth is, with respect to these superficial inflammations, whether they come under the heads of roseola or erythema, so far as the local effect is concerned they are

of very little consequence. The internal affections which give rise to them may be of more or less importance—that is, the disturbed state of the alimentary canal, which produces erythema nodosum, or perhaps any other of these, may be of some consequence; but the cutaneous affection itself is unimportant, for often the erythema nodosum, which is perhaps the worst of them, terminates in resolution. The skin and the subjacent cellular membrane are swelled, red, and inflamed; but in a little time the swelling subsides, the redness goes off, and the affection disappears; so far, therefore, as the local symptoms go, they merely require means of a simple character. A mild saturnine or spirituous lotion, to allay the heat and irritation, will probably be sufficient for this purpose; but you must adopt at the same time such internal treatment as is calculated to remove the disorder from the alimentary canal, which may appear to have produced the affection.

Erysipelas.

We come in the next place to speak of *Erysipelas*, and the affection which we denominate by that term is called popularly *St. Anthony's Fire*. By erysipelas I understand simply inflammation of the skin. I don't regard that term as denoting any particular kind of inflammation capable of affecting other parts, though the term has sometimes been used in that sense. This erysipelatous inflammation has been spoken of in contradistinction to phlegmonous or common inflammation; but when we come to observe the phenomena that are described as characterizing erysipelas, we find that the description applies only to inflammation seated in the skin; and any person would be quite at a loss, I think, to describe erysipelatous inflammation affecting the brain or its membranes, or any other internal organ. I consider, therefore, that erysipelas denotes merely the particular seat of inflammation, and not the kind or nature of the inflammation; and, in fact, erysipelas is merely another name for cutaneous inflammation, or inflammation of the skin.

Now, it is true that the mucous membranes of the body bear a considerable analogy in structure to the integuments. The two are connected together at the outlets of the various mucous canals. Thus it happens that there is a good deal of conformity in their morbid affections between these two structures; thus the mucous membrane may possibly be the seat of inflammation which approximates to erysipelas of the skin; thus we hear people speak of *erysipelatous* sore throat; but I believe we use the term without being able to point out any character by which the affection may be distinguished from ordinary sore throat; indeed, there is no clearly marked sign by which what is

called erysipelatous sore throat may be distinguished from sore throat of any other kind.

In erysipelas we find swelling, heat, increased redness, and pain, affecting a considerable extent of the surface of the body. These effects are produced by simple vascular excitement in the part—sudden distention of its blood vessels, without any effusion of lymph into the texture of the inflamed skin—without any of the deposition which produces the hard and firm swelling of phlegmonous inflammation. Thus we find that erysipelatous inflammation of a part comes on very suddenly, is capable of going off equally suddenly, and leaves behind no trace that is capable of being recognized by examination after death.

The redness in cases of erysipelatous inflammation arises from a state of distention of the most superficial vessels of the body. Hence the colour is usually of a very bright red scarlet. Frequently it is observed that the redness in erysipelas has something of a yellowish cast in it, so that it has been compared to the colour of the rose; and hence erysipelas, in many languages, has received the appellation of *Rose*. Sometimes it is called so in English, and bears the same name in France and in Germany. Under certain states—that is, when the inflammation is not very active, or when the part is in a depending situation, so that the return of the blood takes place under disadvantageous circumstances, the redness may assume a livid coat. The tumefaction in erysipelas is soft and diffused—that is, it extends over a considerable surface. The swelling in these cases arises from a serous effusion into the subcutaneous cellular tissue;—it does not arise from a deposition into the texture of the inflamed skin, but from the effusion of serum into the cellular tissue that lies beneath it. Sometimes the inflammation is not sufficiently active to produce swelling. You may have erysipelas consisting simply of increased redness, without tumefaction of the affected part. The pain that attends erysipelatous inflammation is of a smarting and burning kind, attended with a peculiar sense of heat, and when it is violent, with a very sharp sense of heat; the part is sensibly hotter; you perceive that it is so when you put your hand to it. When the inflammation has arisen to a certain height, you find that effusion takes place from the inflamed vessels on the surface of the skin—that a serous fluid is poured out from them, which elevates the cuticle into vesicles of larger or smaller size. Occasionally the vesicles thus formed are of considerable magnitude, and pretty much resemble those produced by the application of a blister to the skin, which are called in technical language of nosologists, *bulla*. More commonly the inflamed skin in erysipelas becomes covered with an

infinite number of very small vesicles, varying in size from the head of a pin to that of a horse bean, and being so thickly set as to cover the whole surface of the skin. The contents of these vesicles are in the first instance clear, colourless, and transparent; or perhaps have a slight yellow or brownish tint. In a little time they become turbid and yellow. The vesicles then break, their contents escape, and these encrust on the surface of the skin into thin scabs. After continuing adherent for a certain time, these scabs separate, and the skin will be found under them to have recovered its healthy state. When this process is going on in one part of the skin, the inflammation extends in circumference to fresh parts, and the same course takes place in these. There is first redness, heat, and swelling, then vesicles, bursting of these, encrustation, and scabbing; and as this process affects successive parts of the skin, we find that the part that has been first inflamed will have recovered and become completely sound, while the inflammation is going on actively in those parts that have been subsequently attacked in this way. Erysipelatous inflammation not uncommonly extends over a large part, or over the whole surface of the body; and this disposition to extension is a circumstance which particularly characterizes erysipelas, and distinguishes it from phlegmonous inflammation.

We can hardly wonder, when we see how contrasted the phenomena in the two affections are, that some persons have supposed that there is something essentially different in the nature of the two diseases. In phlegmon you have inflammation occurring in, and limited to, a certain spot, going through a certain series of change in that part, and not affecting any other; while in erysipelas the inflammation spreads from its original seat indefinitely, and there is no limit to its extension, in many instances, till it has affected the whole of the body. The seat of the inflammation is different in the two cases. In phlegmon the cellular membrane is the seat of the disease, while in erysipelas it is the skin; and in reference to the spreading, you observe that the skin over the whole body constitutes but one organ; it is one continuous part, homogeneous in structure; and we cannot wonder that when inflammation has once attacked the capillaries of the skin, it should extend by continuity over the whole body. In erysipelas we see none of the tendency to limitation observable in phlegmon, from the circumstance that there is no coagulable lymph effused. In phlegmonous inflammation there is a deposition of lymph into the inflamed textures, which resists its progress; it forms a wall or barricado, which confines the inflammation to a certain part, and prevents it from extending beyond it. Now this effusion of coagulable lymph never

takes place in erysipelas; on the contrary, the disposition to spread seems to be the particular and distinguishing feature of erysipelas. When the inflammation, then, has gone over the whole, or a particular part of the body, and when it has taken the course that I have described, of vesication, and scabbing, and separation of the cuticle, the complaint comes to its natural end.

Sometimes, from the encrustations that are formed by the escape of the contents of these vesicles, superficial ulcerations may occur, though generally when the scab falls off the surface of the skin beneath is sound. There is not much tendency in erysipelas to the production of two circumstances which very commonly take place in phlegmonous inflammation—I mean *suppuration* and *mortification*; we may say, in fact, that suppuration is a very rare occurrence in simple erysipelas. Towards the end or decline of the inflammation, we sometimes find a small formation of matter in the cellular membrane under the skin. Mortification is an uncommon occurrence in simple erysipelas; it may occasionally take place, but we seldom see it. On the other hand simple erysipelas often terminates by the sudden disappearance of the symptoms altogether, or by resolution; but whether vesication takes place or not—whether the complaint ends in this manner, which is the more natural termination, or whether the symptoms disappear suddenly, almost invariably desquamation occurs—the cuticle becomes separated from the skin in consequence of the inflammation, and is detached, constituting the operation which is technically called *desquamation*.

You will naturally suppose that a violent disorder like this cannot affect a large extent of the surface of the skin without being accompanied by symptoms of general disturbance. In many cases of erysipelas considerable fever precedes the development of the inflammation of the skin, so that the inflammation is rather sympathetic of the general disturbance than an original affection. When the inflammation of the skin takes place, it acts sympathetically on the digestive organs and other parts of the economy, and increases the disturbance which has originally produced it. In many cases the inflammation is produced immediately, by direct exciting causes acting on the skin—causes of an irritating kind, injuries, wounds, surgical operations, heating and irritating dressings applied to wounds after the performance of operations—all these, by their directly irritating effects, are capable of producing erysipelatous inflammation—that is, of producing inflammation of the skin which will extend from the original part more or less over the rest of the body.

Now, in estimating the effect of these directly irritating causes, we must consider the state of the constitution of the individual to

whom these causes are applied. A wound or a surgical operation taking place in a person in a very healthy state of body, would not be attended with erysipelas; but if you performed an operation on a person not in very robust health—if you perform an operation on a person who has been in the habit of free living, who has continued his ordinary habits of eating and drinking up to the time of the operation—if you pay no attention to the state of the individual before performing it, you would be very likely to have erysipelas follow. If you perform an operation under any circumstances, and should dress the wound afterwards in an injudicious way, by applying very tight bandages, covering the part with a large quantity of dressing, keeping it excessively hot, leaving the patient to follow an injudicious diet, allowing him to have animal food and other improper things after an operation, it is very probable that erysipelas may take place. In fact, whenever erysipelas takes place after an operation, I believe I may say you will invariably be able to trace it to some neglect, either in the previous preparation, the performance of the operation, the injudicious mode of dressing the wound, or in allowing improper diet after the operation. If you attend carefully to all these, you will not be troubled with erysipelas as a consequence of surgical operations.

Now you will find that an affection which goes under the name of erysipelas, occurs under a variety of circumstances, more or less differing from each other. There is a form of erysipelas affecting the head, which approximates very considerably, in its origin and in the circumstances that accompany it, to those diseases which nosologists have called *exanthemata*—that is, eruptions preceded and accompanied with fever. In erysipelas affecting the head, you have a febrile disturbance of the system for some days before the affection of the skin appears. The patient feels hot, feverish, and thirsty, has a white tongue, his pulse is accelerated, and perhaps strong; he loses his appetite, feels something of nausea and sickness, and then an erysipelatous swelling of some part of the face comes on. The skin becomes red and soft, diffused swelling occurs, and a portion of the skin vesicates; and then the inflammation extends to a fresh part, which goes through the same course. Thus the inflammation creeps over the whole head; the affection occupies perhaps, in its progress, ten days, a fortnight, or three weeks. When it has gone over the whole of the head, it probably declines, and comes to an end without affecting any other part. This has been called *erysipelas exanthematicum*—exanthematous erysipelas; and it must be allowed to be a different inflammation from that which is seen in the skin, and which occurs in consequence of a wound or surgical operation.

Then you have that kind of erysipelas which results from direct irritating causes, where the local inflammation is the first circumstance, and where the constitutional disturbance, when it takes place, is the consequence of the local irritation. The inflammation of the skin which arises in this way, shews itself under different characters, in different instances. In some cases it is confined to the part in which it originally shews itself, and does not extend beyond it. In other instances, it gradually creeps over the whole of the limb in which it is first developed, or it may extend to the trunk and the whole of the body. Thus nosologists have called erysipelas *fixum*—that is, fixed to the part where it first takes place; or *erraticum*—that is, wandering or spreading erysipelas.

Sometimes the effusion of serum into the cellular tissue is a marked feature in the complaint, producing considerable swelling of the limb in which it takes place;—this is called erysipelas *adematodes*.

I should have observed, with respect to the general disturbance that attends these cases of inflammation, that, in some instances, it exhibits the character of what has been called *inflammatory fever*—that is, there is an excited state of the pulse; which is accelerated, full, and strong, with pain of the head, and the other circumstances generally which attend an inflammatory disturbance of the system. In some instances the general disturbance is more particularly marked by the symptoms which denote disturbance of the digestive organs; so that it would constitute what has been called *gastric* or *bilious fever*, where there is a foul and coated state of the tongue, loss of appetite, nausea or sickness, and an irregularity in the performance of the functions of the digestive organs generally. But whether the symptoms should be of one or the other kind that I have now mentioned, in the first instance, they often exhibit an altered character as the complaint proceeds. The general disturbance, which in the first instance may have been active, assumes a different character after the complaint has lasted some time. The pulse, which was strong, may become feeble; the tongue brown and dry, and the general character of the symptoms assume a typhoid appearance. In some instances the head is very considerably affected; and in the latter stages of such affections delirium comes on, and the patient often goes into a state of *coma*, or unconsciousness; a low muttering delirium comes on, and he at last becomes stupid and insensible.

As erysipelas is essentially an inflammatory affection, the treatment of it must be of an antiphlogistic nature. In young and robust persons, where the local and general symptoms are urgent, you will find it necessary to employ pretty active depletion—to

take blood from the arm, to exhibit active aperient medicines, and to follow up these by the use of saline and antimonial medicines; and to employ at the same time a low diet. After bleeding and giving active aperients of calomel and jalap, or calomel and extract of colocynth, you may give the patient a solution of Epsom salts with tartrate of antimony, or you may exhibit calomel and James's powder, with saline draughts in the intervals. In fact, under such circumstances you employ an active antiphlogistic treatment.

I had occasion to mention to you, in speaking of the effect of diet, the case of a gentleman who had a local complaint in the arm, in whom an imprudent indulgence brought on a severe attack of erysipelas. I saw this gentleman about thirty-six hours after the attack came on. The affection was seated in the axilla; and at that time the shoulder, the upper extremity down to the elbow, as well as the anterior part of the chest, were all of the brightest scarlet colour, and as thickly set with minute vesicles as possible. You could hardly put the head of a pin between the vesicles on the surface of the skin. Now the general state of that gentleman was such as might have been expected if any important internal organ had been the seat of active disease. His pulse was accelerated, full, and strong; he was excessively hot and restless; he had a white tongue, and he had lost his appetite;—and this was a state that could not be remedied by simple purging. Being a very free liver, and having had some experience in medicine, he had taken active purgatives, which had operated before I saw him, and yet the symptoms were no better. He was 31 years of age. I deemed it expedient to bleed him, and I removed from his arm thirty ounces of blood, which was very strongly buffed and cupped, and exhibited as good a specimen of inflammatory blood as you would wish to see. I then gave him two grains of calomel and two grains of James's powder every six hours, and in the intermediate times he took doses of saline medicines, and kept constantly applying warm fomentations. By these means, in a few days the inflammation was at an end, and he was convalescent.

You cannot, however, regulate the proceeding in this case simply by a reference to the age of the patient. This occurred in a young man, thirty or thirty-one years of age. I had occasion to remove a tumor from the side of the face of a gentleman rather above sixty. I had performed an operation of a similar kind on him once before, and found on that occasion that there was a considerable inflammatory disposition in his system. I took great pains, by proper diet and giving him purgative medicines, to bring him into a safe state for the operation, before I per-

formed it. I happened to be obliged to leave town for two days, about three or four days after the operation, and I left full instructions as to what was to be done. But when I came back I found that his bowels had not been moved for two days, and that he had got an attack of erysipelatous inflammation over the whole head; the eye-lids were swelled so that the eyes were closed; there was violent vascular disturbance, excessive heat, a frequent, but not a full or strong pulse; a foul white tongue, with a very hot and offensive breath, and the functions of the sensorium, which had been failing for the last twenty-four hours, were now very much oppressed; indeed, at the time I saw him, he was lying in a comatose state. He did not answer questions that were put to him, and, in fact, for the last twelve hours, he had not been able to articulate. His condition was a very precarious one. I immediately thought it necessary to take a large quantity of blood, and I accordingly took from his arm two pints by measure. By the time the evacuation had been accomplished, the sensorium was so much relieved that he perfectly recovered his consciousness; he was able to understand what I said to him, and answered me clearly and rationally. I then administered active aperient medicines, and continued the use of them; and in the course of five or six days that gentleman was quite convalescent. This, then, is the course of proceeding you are to adopt in cases of erysipelas, where the disease is acute, and where the individual is strong and of full habit.

There are other instances, where the inflammation is not so strongly marked—not so active in the symptoms; where the individual is not so robust, and where, of course, you do not resort to means of so active a character. It may be sufficient to take blood locally—perhaps by cupping, perhaps by the application of leeches to the inflamed part, or perhaps by the performance of numerous punctures with the lancet upon the inflamed skin. With respect to the application of leeches to the inflamed skin in erysipelas, I may observe that the ordinary notion of danger, from the bites being likely to add to the inflammation, is totally incorrect. It is true, in particular individuals, leech bites will cause an affection of the skin that is commonly called erysipelas—that is, they will produce swelling, redness, and a state somewhat approaching to that of erysipelas; but when the leeches are applied to an erysipelatous skin, they do not produce any effect of this kind. The abstraction of blood from the vessels of the skin which are in a turgid state, is a direct and very advantageous mode of relieving the affection; and having seen leeches applied in great numbers, over and over again, to an erysipelatous skin, I can assure you there is no

ground for apprehending ill consequences from them. I have not myself seen the practice of puncturing the erysipelatous skin employed, but that course has been recommended by Dr. Dobson, physician to Greenwich Hospital, who alledges that he has employed it frequently, in all cases of erysipelas, with great advantage. The mode he has used, is that of making numerous slight punctures, with the lancet, over the inflamed skin. He says that a large discharge of blood is the consequence of this practice, which produces effectual relief; and, in fact, if the abstraction of blood by leeches is advantageous, we cannot have a doubt that the removal of blood by such punctures is likely to produce much relief. Then, in conjunction with this system of taking blood from the inflamed part, we should of course exhibit aperient and saline medicines, and regulate the diet of the patient. In instances where the tongue is foul and loaded, and where the patient experiences sickness or nausea, we may occasionally derive advantage from the exhibition of an emetic previous to the employment of purgatives.

After the antiphlogistic treatment has been actively used, and in cases where we see the patient at a protracted period of the complaint, when the active inflammatory symptoms have been put a stop to, we often find him in such a state that antiphlogistic means would be totally out of the question. We find him with a small feeble pulse, a great sensation of weakness, and in a state that we should describe as one of obvious debility: of course you would not think of taking blood, or employing lowering means, under such circumstances. In this state, you will find it advantageous to employ tonics, or stimulating remedies, and a diet of a corresponding kind.

Now, in cases where we are in doubt whether we should employ either mild antiphlogistic measures or those of a different kind, I think we may safely exhibit the subcarbonate of ammonia, which is a remedy that some persons rely exclusively upon, in the treatment of erysipelas, and even employ it throughout the whole of the affection. It may be administered in doses of from five to ten grains, in any liquid vehicle, once in three, four, five, or six hours; and you will find it a remedy that may be safely employed in these doubtful cases.

Where the indication is very obvious for the employment of tonic medicines, we should exhibit bark, either in substance or decoction; or, what is still more eligible, the modern form of sulphate of quina, in which the bulk is less and the tonic powers seem equally efficacious. In conjunction with these means we of course allow a better diet. Under such circumstances, we frequently find it advantageous to combine the

employment of direct stimuli, such as wine or porter, with the medicines that I have mentioned. But I should say, that wine must be cautiously used in cases of erysipelas. We are only to administer it in instances where the circulation is very feeble, and where the symptoms of debility are very strongly marked; and even then you should only give it just at the time that those symptoms exist, and not continue its use after they disappear. Because you find it necessary to administer wine, we are not to go on giving it day after day; but when the purpose is answered of producing temporary stimuli to arouse the system, and when the end is answered, then we must leave it off. I think it necessary to be exceedingly cautious in the use of wine in the cases of young persons who are affected with erysipelas. I have hardly seen any instance where persons under the age of puberty would bear the employment of wine under such circumstances.

With respect to the local treatment, it has been generally acknowledged that this has less power in erysipelas than the general measures that I have had occasion to advert to. In the early period of the affection, before vesication shall have taken place—that is, before the complaint has been fully developed—I think you will find that cold applications (as saturnine or spirituous lotions) are the best. But when the inflammation is fully formed, particularly when vesication has taken place, you will, I think, usually find that warm applications, in the shape of fomentations, are more advantageous. But in order to derive the full benefit these are capable of affording, the fomentation must be employed more constantly than is generally done: it is not sufficient for the parts to be fomented for ten or fifteen minutes, three or four times a-day, but the fomentations should be kept constantly applied. You should have a person to attend the patient, and continue a regular succession of warm cloths or flannels to the part; and in this way very great comfort is produced. When vesication has occurred, and encrustation has taken place, it will be necessary to employ some kind of unctuous application to the part; or it may be necessary to apply a simple poultice of bread and water. In the treatment of erysipelas, especially when it occurs in the face, some have recommended the application of flour to the surface, which, I suppose, is tantamount to the confession that local applications are of no use at all; for I cannot suppose that sprinkling a little flour on an inflamed skin can have any virtue or influence in removing the disturbance of the part.

LECTURE XXXV.

Phlegmonous Erysipelas—Treatment by Incision—Urticaria—Herpes.

GENTLEMEN,—The expression *phlegmonous erysipelas* is employed in two senses: it is used to denote either the more acute cases of common erysipelas, that is, those in which the general and local symptoms are highly inflammatory, and in this way the term is used by Cullen; or to denote those cases in which the skin and the cellular membrane are both inflamed together. These latter cases are sometimes described under the denomination of *diffused inflammation of the cellular texture*. It is in this sense that I employ the term, considering it to denote the inflammation at one and the same time of the skin and of the cellular membrane. Now the skin and the cellular membrane are so intimately connected with each other, that we are not at any loss to account for their being inflamed together; in fact, we might rather expect, from observing their close connexion, that they would always suffer together. We find, however, that the skin may be inflamed separately, and that is the case that I have already described to you under the name of *simple erysipelas*. In this case, however, when the inflammation is active, the cellular membrane participates in some degree with the tumefaction that belongs to the skin;—the erysipelas gives rise to a serous effusion into the cellular texture under the skin, and we find that this tumefaction is more considerable in those situations where the cellular texture is more abundant, being particularly marked about the eye-lids. The cellular texture may be the seat of inflammation alone, more especially the deeper seated cellular structure of the limb; but when this becomes actively inflamed, the skin sooner or later participates in the affection.

The affection is termed *phlegmonous* when it is limited to a small part of the cellular membrane, and it is called *diffused* when it occupies a considerable part of the same membrane. Now, in many instances, we find inflammation affecting at one and the same time both the skin and the cellular structure; or we find that the inflammation beginning in the skin, soon extends to the cellular membrane also; or that the inflammation beginning in the cellular membrane, soon spreads to the skin; and whether the inflammation arise in both parts at the same time, or whether it arise in one, and spread to the other, in either case the term *phlegmonous erysipelas* is applied to it; that compound epithet denoting, that the skin and the cellular membrane are both of them in a state of inflammation. Erysipelas being the appropriate term for inflammation of the skin, and phlegmon being the old term applied to inflammation of the cellular mem-

brane, the name is, therefore, very proper, and denotes a case in which the skin and the cellular membrane are both involved.

In its general character, phlegmonous erysipelas resembles simple erysipelas, that is, the inflammation occupies a considerable surface; it spreads with great facility; there is no disposition to limitation; on the contrary, it extends to the neighbouring parts, and soon occupies a considerable extent of the surface, or the entire limb in which it has been developed.

The swelling in the case of phlegmonous erysipelas is firm and resisting, instead of being soft and pitting, as it is in common erysipelas. The skin which is the seat of the affection, is of a bright red colour, tense, and shining; sometimes it is of a bright scarlet tint, sometimes it is of a deeper colour, or even of a somewhat livid hue. But it is the firmness of the swelling—it is the resistance which it affords when you examine it—it is the want of the pitting or softness which belongs to common erysipelas, that particularly distinguishes this form of the disease. There is severe pain, of a burning kind, attending the affection. This is experienced in the early stage of the disease, and it soon becomes very considerable. We shall find, perhaps, in the first instance, when we see a case of this kind, that the redness and swelling may occupy a space as large as the hand; in twenty-four hours there may be double that extent inflamed, and within a short time the whole of the limb may be occupied by these appearances. The cellular membrane, however, very speedily passes into a state of suppuration and sloughing, and in proportion as the inflammation is extending in circumference, the changes that I have just mentioned are proceeding in the situation in which the disease has been first developed. Suppuration, when it occurs in the cellular membrane, like the inflammation itself, is of a different character from what it was in phlegmon. You have not here the deposition of matter in one collection forming an abscess; on the contrary, it is disseminated throughout the cells of the affected structure. You find, in the first place, that there is a serous effusion into the cellular texture, but when the affection proceeds further, the fluid assumes an opaque and purulent character; that it is a thin yellow purulent fluid, which is disseminated through the cellular texture, and which, when you make an incision, you can squeeze out of it. Generally, you do not find it deposited in a particular chamber, like abscess, but disseminated in the cells of the inflamed membrane.

In conjunction with this disseminated or diffused suppuration, you sometimes find a deposition of thick and well-formed matter in particular spots of the adipose membrane,

so that when the part is divided, portions having this character come out at certain points. You find sometimes that such formations of matter take place in small sinuses or tracts, burrowing to a considerable extent in the adipose membrane. In conjunction with this, you will generally find that portions of the cellular membrane turn of a yellow colour,—which portions have lost their vitality; in fact, they have sloughed, and will subsequently be separated. Now these changes you will find particularly to have taken place in that part of the cellular membrane which connects the adipose substance to the fascia, or to the muscles of the limb. The alterations that I now speak of, are not so frequently observed in the stratum of adipose membrane that lies immediately under the skin; but it is the affection which more particularly attacks the *cellular membrane*—that part of this texture which does not contain the fat—the part which lies under the adipose stratum.

In proportion as the affection advances, you find that the external feeling of the part becomes considerably altered. There is no longer the tense and firm swelling which distinguished the affection in its inflammatory stage; but although the part has now a soft feel, yet you cannot say that you can distinguish actual fluctuation, for there is no matter collected into a particular spot, but there is a softness, shewing very clearly that the part is unsound; and this peculiar sensation, or rather the alteration which produces the sensation, occupies a considerable portion of the surface. After a time, the skin becomes a little prominent at some point; the projection ulcerates, and gives way, and thus the matter that is formed in the cellular membrane, is partially discharged. But the opening which is thus made, affords an insufficient exit for the suppuration. A part only of the matter that is formed in the cellular membrane exudes through an aperture of this kind, and the sloughs of the cellular membrane are only partially evacuated by such openings. As the affection advances, however, these openings become more considerable; the collections of matter get rather a freer issue, and the sloughs which have been formed, become loose and detached, and may be drawn out. These sloughs are often considerable in size and number; indeed, when inflammation has been active, and has occupied the whole of the limb, you will find that nearly the entire membrane connecting the adipose tissue to the fascia or muscle, perishes. Thus you may draw out through the opening that has taken place in the way I have described, loose detached shreds of cellular membrane, like pieces of wetted tow, several inches in length, and soaked in pus.

When this process of sloughing has extended considerably under the skin, the vessels which pass from the deeper-seated parts

to the surface become separated; and thus the vascular supply of the skin becomes interrupted. Thus it will happen that portions of skin being undermined and detached in this way, lose their vitality, and a sloughing of the skin will take place, not as the immediate consequence of a violent inflammation, but by a secondary kind of mortification—perishing from the interruption of the vascular supply which they should derive from the parts underneath. In cases of extensive phlegmonous erysipelas, the integuments of an entire portion of the limb, as the leg or thigh, may be completely detached and separated from the subjacent fascia and muscles. Thus there may be an extensive kind of abscess, if we may use the term, between the skin and the subjacent parts.

You will naturally expect that a serious local affection of this kind should be accompanied with corresponding general symptoms. In the first place, you usually find that there are symptoms of active disturbance of the vascular system;—an accelerated and full pulse, heat of skin, a white tongue, thirst, loss of appetite, and so forth. In some instances, the disorder of the digestive organs is more marked;—you do not find so much disturbance of the circulating system, but the functions of the digestive organs suffer more particularly. In proportion as the inflammation with the consequent suppuration and sloughing become more considerable, so does the sympathetic influence of these local disturbances on the circulating and other systems also become augmented, while at the same time the general powers of the patient decline. Thus you have the pulse very rapid and very frequent, but feeble. You find the functions of the sensorium disturbed; the tongue becomes brown and dry; the stomach and digestive organs very much disordered; and, in fact, the patient goes into a state of typhus, and it is in that way he perishes when he dies in the active stage of the inflammation. If, however, the patient has strength enough to struggle through this period of the affection, the extensive local suppuration brings on a state of hectic and diarrhoea, which generally concludes the scene.

The causes of this affection are generally, if not universally, severe local irritation. In many instances, you find phlegmonous erysipelas immediately produced by injuries; especially by such wounds as penetrate into the cellular membrane. It is a very common consequence of compound fractures. It occurs not unfrequently after wounds or injuries of the synovial membranes or bursæ musosæ, such as those seated about the hand or about the patella. It sometimes occurs as a consequence of wounds from venesection; and sometimes in consequence of injuries that are received in dissection.

Phlegmonous erysipelas not unfrequently supervenes in cases of ulcers of the leg, especially if these have been neglected, and where patients continue to exert themselves, and to use the limb imprudently.

You will naturally conclude, that the effects of these causes will be more considerable when they occur in individuals who are of plethoric habit—who are free livers, and who are addicted to habits of intemperance; those who imprudently exert themselves, and who neglect those attentions which their condition, when such phlegmonous erysipelas supervenes, would naturally demand.

In the treatment of these affections, when you consider the serious local inflammatory symptoms, and the general disturbance of the same character which belongs to them, you would suppose that active antiphlogistic treatment would be required. We find, however, that inflammation of the cellular membrane cannot be so immediately controlled by antiphlogistic treatment, as inflammation of various other textures of the body. In strong persons, in young and robust subjects, and in the very commencement of the affection, you may sometimes find it advisable to take blood generally, not so much with a view of arresting the affection in that very early stage, as in order to prevent its development more extensively. However, if the inflammation is already firmly established, we should endeavour to accomplish this object by the local loss of blood through the free application of leeches to the part, while we encourage the bleeding by warm fomentations. When, however, the disease is fully established, we shall find that we do not succeed in putting a stop to it, either by the general loss of blood, or by its free local abstraction by means of leeches. You may employ either of these treatments pretty actively, but you usually find that it does not prevent the progress of the complaint; it not only does not remove the inflammation from the parts in which it has already taken place, but even does not prevent its extending to fresh parts. Under such circumstances we shall find that the most effectual treatment consists in the practice of making an incision through the inflamed textures—a free division of the inflamed skin and cellular membrane; and we shall find that in instances where we have failed to arrest the affection, either by general bleeding or the application of leeches, the mode of treatment that I now allude to will at once and effectually stop it. The plan of making incisions in the inflamed parts has been pretty extensively employed in this country, on the recommendation of Mr. Copland Hutchison, who some years ago published a tract on the subject: he had practised it in the navy, and he had been in the habit of seeing the most severe cases of this kind

in sailors. Having found the inefficacy of the ordinary modes of treatment, he had recourse to the plan I am now alluding to. What he advised was, to make incisions through the inflamed skin and cellular membrane of about an inch and a half or two inches in length, and so numerous as to extend over the part that was the seat of inflammation. If, for instance, it was a case of inflammation affecting the lower extremities, he might make twelve or eighteen such incisions. I have adopted this practice freely; I have employed it in a great number of instances, and can speak strongly as to its beneficial effects. But I have not found it necessary to employ the multiplicity of incisions which has been recommended by Mr. Hutchison. You will commonly find it sufficient to make a single incision and carry it through the middle of the inflamed part, along the whole length of the inflammation, through the skin and integuments; and that one such cut will answer all the useful purposes which he has described as being produced by more numerous incisions. If the leg were the seat of this affection—the posterior and inner part of the leg, for example—you might commence the incision at the knee, and carry it through the middle of the inflamed part to the ankle, or as low as the inflammation extended, dividing the skin and the whole depth of the cellular membrane down to the fascia. It is not necessary to go deeper than that. This incision is to be accomplished by means of the ordinary sharp-pointed double-edged bistoury. You take it between the finger and thumb, allowing as much of the instrument to project as will make the necessary incision, and then just carry it gradually along. If you have not divided the whole depth of the inflamed cellular membrane, which is the seat of inflammation, you can, with the same instrument, easily cut through the remaining parts where any portion of your incision may be defective.

The immediate effect of this incision is a very copious discharge of blood from the vessels of the inflamed part; and the loss of blood in this way is the most effectual mode that can be employed, because it comes immediately from the vessels that are the seat of inflammation. You find the arteries and veins of the limb thus divided bleed very freely, so that 20, 30, or even sometimes 40 ounces of blood, will flow from an incision of this kind in as short a time as you could get it from a large opening in a vein of the arm; you will indeed be surprised at the short time in which a large quantity of blood actually flows from an incision of this kind. You find the blood running freely in a large stream out of the subcutaneous veins you have divided; and a great number of arteries pumping out the blood in jets by numerous orifices. By the mode in which

the blood is thus discharged, you can account for the manner in which such a large quantity of it is lost. The effect of this is not simply to lessen the degree of inflammation, but to take off the tension of the part also; so that you find, by the time the flow of blood has ceased, that the part which before was of a bright shining red, becomes of the natural paleness of the skin; and the part that before was tense and shining, becomes wrinkled, giving the most satisfactory proof that the tension is at an end; and the patient obtains the most decided relief—a fact that I have verified by repeated observation.

Now this free loss of blood is a circumstance calculated to put you on your guard in adopting this treatment. You may find that the patient loses rather more than you may like—he might lose more than he could bear, and it might consequently cost him his life. You must, therefore, watch the patient—you must not quit him; or, at all events, you must leave him with some one to take care that the loss of blood does not go beyond a safe point. If the blood is running out freely, and the pulse is sinking, you must adopt means to stop the hæmorrhage forthwith. You can do this sometimes by elevating the limb, and retaining it in that position; or by pressure on the part out of which the blood flows; or sometimes you find it necessary to take up one or two of the bleeding vessels, and in that way you generally arrest the hæmorrhage, if it be troublesome.

The plan of incision in phlegmonous erysipelas may be adopted at all periods of the complaint. If you employ it before suppuration and sloughing have taken place, you will prevent the occurrence of those changes; if you employ it after they have commenced, you will prevent the extension of the inflammation, and thus will limit the extent of the suppuration and sloughing. I have always seen, where this plan has been put in practice effectually, that the inflammation has been decidedly stopped; and I have not found any fresh parts affected after the incision has been made. At the same time the incision which you thus make affords the freest discharge for the matter that is formed in the cellular membrane, and for the sloughs when they have become detached. The small opening which takes place in the skin by the natural process of the disease, as I have already intimated, forms a very insufficient outlet; but the free aperture you make by an incision of this kind, permits a much more effectual discharge. Even in the advanced period of the affection, when considerable sloughs have been formed and detached, when extensive suppurations have taken place, and when the integuments are all detached extensively from the subjacent parts, you will find that a free opening prevents the burrowing and lodgment of the matter, and

by giving ready issue to the suppuration and the sloughs, greatly promotes the healing process.

When a case of this kind has been allowed to follow its natural progress—when very considerable portions of the cellular membrane of the limb have been lost by sloughing and suppuration, you will not wonder that after healing has occurred the parts become preternaturally connected together—that considerable rigidity occurs, so that the motions of the joints in that part of the limb which is the seat of the inflammation, become considerably impaired. These are common consequences, which take place even if the patient recover, and afford a powerful reason for adopting any means which are calculated to limit the progress and check the advance of this serious affection, independently of the danger to the life of the patient, which belongs to the disease when it is allowed to go on unchecked. After the incision has been made in the way that I have mentioned, you will in general find it sufficient to employ simple dressings. A common poultice applied to the part, and a simple dressing afterwards, will be sufficient for the purpose in most cases. If the process of granulation does not seem to go on actively enough, you may dress the wound with yellow basilicon ointment, applying it under the poultice. You will find that the incisions which are made in this way heal very rapidly and very regularly, when the inflammation has been relieved, which it usually is by this treatment. Some persons have conceived that in the state of inflammation which occurs in phlegmonous erysipelas, the infliction of such an incision would of itself materially aggravate the local mischief—it has been considered that this irritation might occasion ulceration of an intractable kind; but, on the contrary, we find the processes of granulation and restoration generally go on with great activity and with great rapidity in these cases.

With respect to the general treatment of this disease, I need not add any thing to what I have had occasion to point out to you in speaking of simple erysipelas. In the active stage you must, of course, use means calculated to lessen the inflammation. If the patient become weakened and exhausted in the subsequent stages of the affection, you must employ measures of a different kind.

I remember an instance of a poor woman being brought to this hospital with a very serious affection of the lower extremities of the nature that I have above alluded to, in which the treatment that I have mentioned was attended with the most marked and beneficial results. This was a woman who had been previously in the hospital with a sore leg—an ulcer situated near the ankle: she had gone out with the sore nearly healed, but was obliged to exert herself considerably

in order to gain her livelihood ; thus a state of inflammation had arisen in the ulceration, and this had in a short time produced phlegmonous erysipelas, affecting the whole of the leg and thigh, and she was brought to the hospital in that state, being then in the seventh month of pregnancy. When I saw her in the evening (for she was brought in late) the condition of the leg and thigh was really quite frightful ; the limb was enormously swollen—the swelling extending over both the leg and thigh ; the leg from the lower part near the ankle up to the knee was of a bright red colour, with a firm swelling and vesications—the whole of the skin was in a state of vesication ; the foot and ankle enlarged by œdematous tumefaction ; the thigh at least twice the size of the limb, and of a bright red, extending along the inner side towards the groin. The rest of the limb was œdematous, and I do not know that I ever saw a case where the appearances were more unfavourable—the inflammation seemed so violent and extensive. She was so reduced when she was brought to the hospital, it being the winter time, that it was found necessary, from the low state of her pulse, to give her a little wine and water. She had taken a little of this, and had somewhat recovered when I saw her. Viewing the very serious nature of the local disease, and considering her state of pregnancy, I really thought it highly probable, that whatever treatment was adopted, the case would terminate unfavourably, and I mentioned my suspicions to the gentlemen present. However, I determined on giving her a chance, by adopting the plan that I have just recommended—that of incision. I accordingly made a cut, extending from the ham down to the inner ankle, through the skin and cellular membrane, carrying it along the middle of the inflamed part. The inflammation in this case also extended, though in a less degree, above the knee towards the groin ; but I did not like to cut exactly the whole length from the groin to the ankle, and I was therefore satisfied with making an incision along the whole of the lower part of the limb. She lost twenty ounces of blood from this incision, and she then took a large dose of Dover's powder. She was immediately relieved by the loss of blood, passed a very tranquil comfortable night, sleeping a good deal, and was greatly better next day. I need not repeat the history of the case minutely, for it is enough to say, that although she remained perhaps two, three, or four weeks in the hospital, she continued to go on favourably ; and from this time no bad symptom occurred—the pain never came on again. I believe some small formation of matter took place at the lower part of the thigh—that is, higher up than where the incision was commenced ; but with the exception of this the case went

on as favourably as it could do. Although the incision did not occupy the whole of the inflamed part, it seemed to put a stop to the inflammatory process, which never extended after the incision was made. It was attended with a diminution of the redness of the surrounding parts, and of the tension of the integuments, which clearly shewed that the inflammatory affection was arrested ; and, in fact, nothing could be more favourable than the progress of the case after the incision that I have mentioned to you had been made.

There was another instance in which the effect of this treatment was very remarkable, under circumstances perhaps yet more unpromising. It was that of a student at this hospital who received a wound on his finger in dissecting, which was followed by mortification of the last phalanx. The wound of the finger had been followed by violent inflammation of the hand, fore-arm, and arm, with most serious inflammatory symptoms generally ; and this went on in spite of very active means, including resection, the local loss of blood, and other suitable measures, for about seven or eight days. This patient was under the care of Mr. Earle, who employed the most judicious means to remove the local inflammation. About the time that I have mentioned I saw this patient with Mr. Earle, and after considering the case, we determined to adopt the mode of treatment by incision. I should mention that this gentleman seemed almost in a desperate condition, with a very rapid feeble pulse, a countenance expressive of great anxiety, with a contraction of the features, a sharpness in the appearance of the face, and a general aspect that portended the greatest danger. He had not got any rest for several nights previously. The fore-arm and arm were swollen, and of a bright red colour up to the shoulder. This gentleman was in a state in which probably no one would have thought of proposing the abstraction of blood ; it would have been looked upon as the mode best calculated to hasten his decease. In this instance either two or three incisions were made, I hardly remember which. An incision was made along the arm, and I believe two in the fore-arm ; one over the radius, and one over the ulna, through the inflamed skin and cellular membrane. After the incisions were made the arm was enveloped in warm cloths, and the bed clothes were laid comfortably over him, for he was, of course, too ill to be up ; his extreme exhaustion would admit of no position but the recumbent one. No particular attention was paid to him for some little time, and when we had left the house an alarm was given that he was worse, and, in fact, he fainted. When his friends came to examine him, and to put aside the bed clothes, it was found that an immense quan-

tity of blood had flowed from the incision. The father told me that he considered that there was more than three pounds of blood lost; it was taken up by tea cupful and put into a washhand basin, cupful after cupful; and this produced, as you may well suppose, a state of syncope. But although it might have been inferred that such a loss of blood would have had a serious effect, it seemed to have acted quite differently from what it would otherwise have done, in consequence of being drawn from the vessels of the inflamed part; and, in fact, the gentleman derived the greatest relief from the depletion; he speedily recovered, and ultimately got quite well.

Urticaria.

Urticaria is an exanthematous affection of the skin. The name by which it is well known in common language is that of *nettle rash*, and the corresponding names in other languages denote the circumstance of the affection resembling that inflammation of the skin which is produced by the contact of the ordinary stinging nettle. It consists of tubercular elevations, sometimes a little redder, but sometimes indeed paler than the skin itself, arising in the course of the night and declining again in the day, attended with a very severe sense of itching, pain, and burning heat.

These tubercular risings of the skin sometimes appear in the form of small circular elevations, perhaps not larger than half a pea; sometimes they assume the form of long elevations, constituting what are called *wheels*—appearances similar to the effects produced by the stroke of a stick, or whip, on the skin; sometimes they appear in pretty large raised patches; I have sometimes seen them as large as the palm of my hand, though it is not common to see them of that magnitude. These constitute what are called the *urticaria conferta*, or *tuberosa*, of the cutaneous nosologists. The skin of individuals in whom these appearances take place is particularly prone to inflammation; it is easily excited, for in such individuals very commonly mere pressure on the skin, or scratching it, will raise elevations of this kind. You can see them produced before your eyes. These elevations generally take place during the night; the patient is kept awake and prevented from resting by an intolerable sense of heat and itching. These lumps arise, they become troublesome for a certain length of time, then the itching goes off and the tubercles disappear; but a fresh set will come on the succeeding night.

There are more kinds of this affection than one; there is *urticaria perstans*—that is, a constant or continued state of nettle rash.

Generally speaking, these elevations take place on the skin in its natural state; but they are occasionally seen to occur on inflamed

patches of the skin, and this constitutes the *urticaria febrilis* of the cutaneous nosologists. I believe this affection of the skin is always dependent on the state of the digestive organs; very commonly it is preceded and accompanied by unequivocal symptoms of such disorder—that is, by loss of appetite, by nausea, and sickness. It is sometimes brought on by particular articles of food that disagree with the stomach—more especially by some kinds of shell fish. Now the muscle, which in some places is commonly taken as an article of food, not unfrequently produces this affection; and in some parts of the country, where the above is a frequent article of food, and where persons are consequently acquainted with this effect, it is known by the name of *muscle rash*. Not only other shell fish produce this effect, but also other articles of food. Again, it will be produced by gluttony or intemperance generally—by taking too much of those articles that stimulate and act unfavourably on the stomach.

Since this is the cause of the affection, of course the mode of remedying it is tolerably obvious. If the stomach be loaded, or in a foul oppressed state, from such practices as I have mentioned to you, the obvious remedy is to clear it by an emetic; and experience has so fully established the efficacy of this plan, that we may say in most cases this remedy will put a stop to the nettle rash. When you have administered the emetic, you may then purge the patient; and at the same time you should regulate his diet, of course prohibiting any thing that seems obviously to have caused the attack.

Sometimes the complaint will last for a considerable time, and it will thus continue, in spite of such a mode of treatment as you might suppose calculated to put a stop to it. I remember being consulted in the case of an elderly person, who told me that he had not had a comfortable night's rest for a month. He had been troubled by nettle rash for that length of time, and had taken a great deal of medicine—a vast quantity of opening medicine—but it did him no good. Seeing he had taken opening medicine, and there was no good result from it, I doubted whether I should give him an emetic; but I thought I would try it, and accordingly I prescribed an emetic of the ordinary description—a scruple of ipecacuanha with a grain of tartrate of antimony. He took it, and he was effectually relieved; so that he did not want any other treatment.

Herpes.

The name *herpes* is given to an eruption of minute transparent vesicles, taking place on inflamed patches of the skin. You have, in the first place, a sense of heat and tingling occurring in some part of the body. You see a portion, or some two or three portions of the skin become inflamed in small

patches, and very soon you find them rising up into a set or group of minute, transparent, watery vesicles. These enlarge, and in the course of two or three days they lose their transparent state, becoming brown, or yellow, and opaque. The contents of the vesicles escape, encrust upon the surface, form scabs, which fall off and leave the surface tolerably sound. You have a succession of these inflamed patches of the skin, going through the same process. Thus you find, in one and the same case, some portions of the skin in which the vesicles have just arisen, and where they are small and transparent; others in which the contents begin to change colour; others in which the encrustation is going on. The affection generally lasts ten days, a fortnight, or perhaps three weeks, and is attended with more or less of febrile disturbance; and then it goes off spontaneously, and leaves the patient well.

Now one of the most common of these affections is the formation of clusters of vesicles of this kind, which ultimately constitute a half girdle, or band, round the trunk of the body—this is called *shingles*; in technical language, *herpes zoster*, or *zona*. It is strange enough that this affection has been described by many, and those of pretty extensive practice, as a form of erysipelas, though there is no resemblance between the complaints. Cullen, in his *Nosology*, calls it erysipelas. Franck, Richter, and Boyer, state that herpes zoster—that is, the shingles—is a species of erysipelas, though the characters of the complaint are quite dissimilar. The shingles take place upon the trunk of the body; wherever it forms, it extends towards the median line, both anteriorly and posteriorly, and it limits itself to one half of the body. You have a succession of inflamed patches, and a succession of vesicles taking place in the patches. It approaches the linea alba in front, and the vertebral column behind; so that is not a zone, or girdle, but half a girdle. A strange notion has existed, which is as old as the time of Pliny, that if this affection extends completely round the body, it will terminate fatally; however there is no ground for it. It is said sometimes to pass the median line, but I never saw it do so. The expression of Pliny is, “*Ignis sacri plura sunt genera, inter quæ medium hominem ambiens, qui zoster appellatur et enecat, si cinxerit*”—it kills if it surround the body.

In shingles, or herpes zoster, the vesicles vary considerably in size—from that of a pin's head to the size of an almond. Now the latter comes under the technical denomination of what cutaneous nosologists have called *bullæ*. Herpes is placed among the vesiculæ by Drs. Willan and Bateman; but zoster by Boyer among the class *bulle*. I

believe it is mostly seen upon the abdomen and lower part of the chest. I have seen it occurring on the chest, spreading over the shoulder to the arm. I have also seen it extend longitudinally down to the hip. But in this situation, as well as where it is seated on the chest, it is confined to one half of the body, and does not go beyond that. This disease is generally attended by a febrile disturbance, and some derangement of the digestive organs.

So far as the cutaneous affection goes, it is unimportant; but the febrile symptoms, and the state of the digestive organs, require mild antiphlogistic treatment, the exhibition of aperient medicines, of saline and antimonial medicines, with reduced diet, and rest. There is often a great deal of local pain produced by the inflammation and vesication; and mild local applications are best suited to this state—simple saturnine or spirituous lotions;—common white ointment, or elder flower ointment, may be applied, or a soft poultice, if it proceed to encrustation.

The *herpes labialis* is that form of vesicular disease which occurs about the lips, in conjunction with some fevers, or towards their decline. Here you observe the progress of the complaint very distinctly—first the inflammation, next the formation of vesicles that become opaque and purulent, and then the bursting of the vesicles and the formation of crusts, or scabs.

Herpes præputialis.—Herpes occurring on the prepuce is a complaint that might be confounded with a venereal affection. Some inflamed patches occur on the prepuce—small groups of little vesicles take place upon it. Perhaps from six to twelve minute vesicles will occur on a patch of this kind, and there go through the process that I have mentioned. First they are small, transparent, watery vesicles; next they become opaque, and then they shrivel and dry up, while you have perhaps two or three patches forming in succession. The truth is, if you see them in a vesicular state, I do not know how it is possible to confound them with the venereal disease, they are so dissimilar; but it is well to be aware of the possible occurrence of such an affection, that when you meet with it you may know at once that it has nothing at all of a venereal character.

This affection, herpes, may occur on a limb, and extend the whole length of it. It is essentially the same as herpes zoster, differing only in situation. It has been described by Bateman as *herpes phlyctænodes*.

LECTURE XXXVI.

Scabies—Eczema—Variola—Vaccinia.

Our next subject, gentlemen, is that vulgar disease called *itch*, to which we give the more polite appellation of *scabies*, or *psora*. There is some doubt respecting the situation which should be allotted to this complaint in the arrangement of cutaneous diseases; for we see it sometimes in the form of vesicles, sometimes in that of pustules, sometimes in the form of pimples—these forms appearing either separately or conjointly; so that it would seem to have nearly an equal claim to a place in three of the orders established by Dr. Willan. This circumstance will lead you to the conclusion that, although the arrangement proposed by Dr. Willan, and adopted by others, is convenient, as allowing of a distribution of the varied affections of the skin, yet we are not to conceive that these divisions indicate, in all instances, an essential difference in the nature of the affections they include; for here we see that one and the same affection may exhibit, at the same time, appearances which might lead to its arrangement under three different orders of cutaneous affection. The more common form of itch consists of an eruption of small, clear, transparent vesicles, on an uninfamed skin. These appear, in the first place, on the hands; they usually shew themselves about the intervals of the fingers, or about the wrist, and from that situation they spread over the upper extremities, and from thence over the body generally; excepting, however, the head and face. I do not say that the itch *never* appears on the face; but, at all events, it is an extremely rare occurrence to see it there.

As this complaint is contagious, it may be contracted by shaking hands; but as there is an exception of this affection from the face, you will understand that there is no fear of catching it by kissing. The vesicles that I have now mentioned extend over the body generally; they are pretty universally disseminated; they are not confined to one part, nor do they appear in distinct patches, or groups; and in this respect itch is distinguished from some affections of the skin which, in other points, bear a resemblance to it. The most troublesome circumstance belonging to it is that from which it derives its English name—the intolerable itching which accompanies it. It is an itching that people cannot bear, and, in spite of themselves, they seek relief in scratching. Thus it happens that the minute watery vesicles of which the disease consists become broken, and the character of the affection alters; for you have superficial encrustation, with an intermixture of slightly bloody discharge produced by the scratching. The vesicles, however, if left to themselves, supposing they were not at all broken by that

kind of external interference that I have alluded to, would give way; their contents would escape, superficial ulceration would follow from this natural process, and slight encrustation would occur in the parts which are affected by the pustules.

This affection is not preceded, nor is it accompanied by, any febrile or other derangement of the constitution. With the body covered all over with the eruption of itch, the patient, in other respects, may be in a condition of perfect health; and generally speaking, I may observe to you, that, however thickly these watery vesicles may appear in any part of the body, that portion of the skin which exhibits them is not inflamed, but usually retains its natural paleness. The eruption, therefore, of itch, in the form I am now alluding to, consists simply in the development of these small and perfectly clear watery vesicles.

Frequently we have the itch in the form of pustules, from the elevation of the cuticle by the secretion under it of a bright yellow purulent fluid. These occur about the fingers—more commonly in the intervals between them. Frequently you have them placed between the thumb and fore-finger, and about the wrist; they will extend to the palm of the hand, and from this situation they will proceed along the extremity, and affect the fore and upper arm. You have them in the same way upon the feet and legs, but you do not so commonly see these pustules on the trunk of the body.

The pustules of itch vary in their size, from a large pin's head to that of a sixpence; and sometimes you see them almost as large as a shilling, particularly where the cuticle is thick, as in the palm of the hand. Now as this form of the disease is attended with more of inflammatory affection of the skin, the basis of these large bright-yellow pustules is often inflamed; and when there are several of them seated near together, the part which they occupy is not only considerably inflamed, but it is generally swollen. There is a serous effusion into the cellular texture; and when there is a considerable number of these formed on the hand, the wrist, and the fore-arm (or in the same way in the lower extremities), you will find so serious a local irritation as to produce considerable fever—a degree of feverish disturbance of the constitution that may actually require the use of the lancet; a circumstance which you never observe in cases of the small watery vesicle. This is a form of the disease which is more particularly observed in rather young persons, and in those who are in a state of plethora, with fulness of habit; in those, in short, who are young and robust.

Now whether the disease shews itself in the form of vesicles or pustules, we do not find that it is equally disseminated over the whole body. Although it extends more or

less over the frame, we find the appearance most obvious in those situations where the skin is liable to friction, from the dress or from the natural motions of the part; we find, therefore, that there is the greatest quantity of itchy eruption about the wrist, the bend of the arm, and the arm-pits—about the waist, and about the knees and ham.

I should have observed to you also, about the itching, that it is not a symptom which is always equally troublesome. During the day-time, when the skin is cool, the patient does not feel a great deal of annoyance from it. But whenever the individual is heated (such as when he becomes warm in bed, or after eating and drinking heartily, so as to excite the circulation), then the itching sensation becomes troublesome, and almost intolerable.

Then there is a third form of the affection, in which it appears in the shape of *pimples* on the skin, seldom distinctly prominent, but you can feel them by passing the fingers over the surface. When you make the examination more narrowly, you will see minute elevations, which are called pimples, or *papulae*. It is said that if you examine these very carefully you will find minute vesicles on their centre. You may have all these three forms mixed together, or see them in some measure separately. I may observe to you, however, that you will not see the pustular form of itch without an intermixture of vesicles. As to the pustules in the itch, if you saw one or two separately, they might exhibit an appearance that you would not immediately recognize; but you usually see a multiplicity of them; and not only so, but you see around them the small, clear, transparent vesicles which immediately point out to you the nature of the affection.

The itch is most prevalent among the lower orders of the people, and its origin and propagation are particularly favoured by the neglect of cleanliness, whether in respect to person or dress, which is so common amongst them. Now, as they have such frequent opportunities of observing it, it seems that they have distinguished very accurately the different forms of the affection. Dr. Willan states, that he found among the common people that there was a distinction of four forms of itch, which they call the *rank* itch, the *watery* itch, the *pocky* itch, and the *scorbutic* itch; and he has really paid a great compliment to the accuracy of popular discrimination, by adopting these distinctions and introducing them, under scientific names, into his cutaneous nosology. The *rank* itch he calls scabies, *papuliformis*—that in which the pimply elevations of the skin are more prominent. The *watery* itch he calls scabies *lymphatica*—consisting of the more ordinary form of the complaint,

with clear, transparent, watery vesicles. The *pocky* itch he calls scabies *purulenta*. I may observe, that it is not meant to indicate that there is any mixture of pox, or syphilis with the itch; it is only used to denote the form of pustule, or pox in common language. And lastly, scabies *cachectica*, or scorbutic itch, in which we are apt to find a combination of various forms, but principally an intermixture with large patches of lichen, psoriasis, or impetigo, in elderly persons, with some other modifications of cutaneous disease.

Now the itch originates and is propagated by contagion. We are not aware that it ever arises from any internal cause, or from the state of the constitution in any individual. So far as our knowledge goes, itch would not take place in any person except by the communication of some poisonous or contagious matter from an individual previously affected with the complaint. Then there seems to be no natural end of the affection: the particular appearances go through a certain stage, and come to an end—that is, the watery vesicles or pustules of itch break, encrust, form superficial ulcerations, and then come to a termination. But you have a succession of similar appearances taking place after those that first have shewn themselves; these also come to an end, and then the disease attacks fresh parts of the body. Thus there is no reason why the itch should not last the whole life of an individual; in fact, in many instances, it lasts a great number of years, among the lower orders, who are not attentive to cleanliness, who do not change their clothes nor their linen, nor wash their bodies sufficiently often. I may observe to you, however, that the disease is not by any means so contagious as is imagined. People have a great horror of the itch, and would almost rather hear of some more serious calamity than that an individual connected with the family had got this complaint. However, the danger of infection is exaggerated by the fear we feel on the subject;—there is no very great risk of our having the complaint propagated in a family. Among persons who are cleanly, if the itch is contracted, it will be confined, perhaps, to a small portion of the body. It will not extend from one individual to another, in decent families—that is, in those families where general habits of cleanliness exist among all the individuals. I have known several instances of one individual in a family having the itch, without other persons with whom he has been in the habit of free intercourse catching the complaint.

I remember a clergyman calling on me with two of his daughters, one of whom, he said, had got an obstinate affection of the skin. They were two nicely-dressed young ladies. I begged her to let me see it; and when she uncovered her arm it displayed a

specimen of the itch—as fine a specimen as I ever saw. I could not help believing that such was the complaint. The gentleman said that some persons had supposed it was the itch, and that means had been used accordingly, but that they were not effective. I told him that my opinion was decidedly that it was itch—that I could not view it in any other light, and that if the proper treatment were adopted the lady would get free from it. He said it could not be the itch; for she had been in the habit of sleeping with her sister all the time she had had it, which was nearly a year, and the sister had not contracted the complaint. I told him I could only recommend a certain treatment—one calculated to cure the itch. This was put into practice, and she was completely and speedily cured.

Now the appearances which attend itch may belong to some other affections of the skin; and thus it becomes important to distinguish this complaint from those which resemble it. I may state to you generally, that the particular circumstances from which the complaint derives its name—that of intense itching—the absence of febrile or any other disturbance of the system, and the uninfamed state of the skin on which these appearances take place, are the principal circumstances which characterize it. Also the great diffusion of the affection over the body, its dissemination without being confined to any part, or the appearances being collected in particular patches or parts of the body. These are the main circumstances that characterize the itch.

Now the great remedy for itch is brimstone; and if there be any kind of remedy which can be deemed a specific for any complaint, I think we must regard brimstone in that light—as a specific remedy for the itch. The external application of it, in the form of ointment, to the affected skin, is the most effective mode of employing it. The brimstone ointment consists, according to different prescriptions, of different proportions of brimstone. Thus, in the London pharmacopœia, the *unguentum sulphuris* is made by a combination of three ounces of sulphur with eight ounces of lard;—the sulphur ointment, which is recommended by M. Rayer, whose work on Cutaneous Diseases I have already had occasion to mention to you, consists of one part of sulphur and two of lard. He mentions another formula, which consists of two parts of sulphur, one part subcarb. of potash, and one part of lard, incorporated into an ointment. The unpleasant smell of sulphur, and the mode in which it contaminates all the dress of the individual, have made people anxious to mix it with something that should destroy the smell, or to find out some other mode of remedying the disease that is not exposed to this objection. Dr. Bateman, in his work on

Diseases of the Skin, gives a formula in which sulphur and lard are combined in equal proportions, but with which as much bergamot and cinnabar as will give it an agreeable smell and colour, and a little subcarbonate of potash and rose-water, are united. Perhaps it is a question of taste, but if I were so unfortunate as to have the complaint, I believe I should use sulphur ointment alone. I do not like using this mixture of sweets and stinks together; it is like administering food and physic, and you know that I have a great objection to that. The mode of using it consists first in cleansing the surface of the body, using the warm-bath, and having the body well washed with soap and warm water. Then the sulphur ointment is to be plentifully smeared over all the parts of the skin on which there is any appearance of the affection. The object is not to rub in the ointment as you rub in mercury ointment for the pox, but only to cover the affected parts plentifully with it. Then the patient should put on a suit of under garments—stockings, drawers, flannel shirt with sleeves, and gloves, so as to confine the ointment thus employed to the surface of the body; and these garments are to be worn till the treatment is at an end. The patient should repeat this sulphureous unction night and morning, and let him do the same for three or four successive days; then go into the warm-bath, and cleanse the surface well with warm water and soap, and you will be able to see whether there is any appearance of fresh eruption on any part; if so, you must repeat the process.

Now as to the time required for curing the disease, doctors seem to differ. I see that one practitioner of considerable authority, on diseases of the skin, says that itch may be cured in this way in twenty-four hours. I should not consider a person likely to get cured in that time; I cannot say that I ever saw it cured in so short a period. M. Rayer, in whose judgment I place great confidence, and who has had great practice in this affection—for the itch appears to be very common among his countrymen,—says that this mode of proceeding will cure the itch in fifteen days. I think him the nearer the mark of the two, according to my experience. However I believe that, in general, by using the ointment freely, it may be cured in less than that; but if it be inveterate (or rank, as the common people call it), I do not know that it can.

I may observe, that the application of the ointment is sometimes attended with a very copious appearance of the eruption. The common people say that the ointment brings the disease out; and I do not know whether the expression be not a correct one, for we see the eruption come out more abundantly 24 or 48 hours after using the ointment. I believe the various attempts to use sulphur

in other forms less objectionable than that of ointment, have not led to any useful results. Sulphurous baths have been used: four ounces of the sulphuret of potash may be mixed with as much water as is necessary for a warm bath; the surface may be washed over plentifully with a solution of sulphuret of potash, in the proportion of one or two drachms to a pint of water. Sulphur may be applied in the form of a fumigation or vapour—sulphur vapour baths. An ointment has been used composed of the strong sulphuric acid mixed with lard, in the proportion of half a drachm, or a drachm, to an ounce of lard. This ointment does not possess the disagreeable smell of common sulphur ointment, but it corrodes the linen of the patient, and is so far disagreeable. Then again, certain substances have been mixed with the sulphur. The white hellebore has been considered to have some efficacy as a remedy for itch. The unguentum sulphuris compositum of the London Pharmacopœia contains sulphur in conjunction with the root of white hellebore. There is an ointment which goes by the name of *Jusser* (so called after its inventor) much used in Hungary, that consists of the flowers of sulphur, sulphate of zinc, and laurel berries, in equal parts, mixed in the form of a liniment with olive or linseed oil; and this is to be rubbed on the surface of the body. Now I have sometimes seen persons employ all these various modes of proceeding, but I do not think that there is any thing so effectual, so beneficial, and so much to be relied on, as the simple application of common sulphur ointment. They may be capable of curing the complaint, but the time required is considerably longer, and the effect of the remedy much less certain.

A question will naturally occur, whether sulphur may be administered internally with any effect, or whether the cure can be promoted by it? I cannot distinctly say whether it can be cured by the internal use of sulphur or not, having been in the habit of seeing it employed in the way I have mentioned. I believe, though perhaps it may not cure the complaint, it may assist other means. You may therefore use sulphur mixed with treacle, in the form of an electuary, in aid of the external applications.

Eczema.

There is a genus of vesicular cutaneous diseases which has been called by Drs. Willan and Bateman *eczema*—a Greek term. I have already had occasion to mention the form of this affection produced by mercury—*eczema mercuriale*, or *rubrum*. Frequently you have an eruption of vesicles, preceded generally with a little inflammation of the skin, in consequence of some immediate external irritant. It is a form of cutaneous disease owing its origin to the direct application of some obvious cause. Thus you

have *eczema solare*—that is, the appearance of vesicles in consequence of exposure to strong heat during summer. Most individuals have it either on the face or on the hands, when these parts have been much exposed to the sun. Then it is seen in those individuals in whom any part of the body is habitually exposed to sources of irritation, such as grocers, bakers, bricklayers, and others, in whom certain parts are covered frequently with a minute powder or dust. These persons become the subjects of an affection of this kind; and in popular language these affections are known by the names of *grocers' itch*, *bakers' itch*, and *bricklayers' itch*. Sometimes it is in the form of watery vesicles, sometimes of small pustules, sometimes of an inflammatory state of the skin, or what is termed a *chapped* state of the cuticle, approaching to the condition called psoriasis.

In all these instances it is, of course, a matter of obvious necessity to remove the cause—to prevent the application of the external irritants which produce these effects; and, generally speaking, that is sufficient to cure this affection. Dr. Thompson, who has published a recent edition of Dr. Bateman's *Synopsis of Cutaneous Affections*, mentions that in certain of these affections, where there is a good deal of irritation and heat of the part, benefit has sometimes been derived from hydrocyanic acid locally applied. He gives one or two formulæ; for instance, a drachm of the hydrocyanic or prussic acid in eight ounces of emulsion of bitter almonds; half an ounce of prussic acid, with half a drachm of acetate of lead in sixteen ounces of distilled water, forming a lotion, with which the parts are to be bathed in the course of the day.

Now we occasionally see cases of this character, consisting in the appearance of watery vesicles, without our being able to trace the application of any external irritation, and without our being able to account for it by the existence of any internal disease. I remember an instance of a young woman who was under my care at St. Bartholomew's hospital, who had a large node on one ulna, and a considerable swelling both of the tibia and fibula. She was about 23 years of age. There was a considerable swelling, with ulceration, over the tibia. She was thin and pallid, and seemed in a bad state of health. By the means that were employed the ulceration on the legs became greatly diminished. She was then affected by a vesicular eruption, first in one hand and then in the other. There were a number of clear, transparent vesicles, varying in size from that of a pin's head to a large bean, formed on the palm of the hand and palmar surface of the fingers and thumbs, extending a little way along the corresponding aspect of the fore arm, with hardly any discolouration of the skin; some heat and tingling, but

not any violent itching. These vesicles began by exhibiting the appearance of transparent fluid, but some of them soon became a little turbid; they then gave way, and broke—a superficial encrustation formed, the cuticle peeled off from the hands, and in the space of five or six days the complaint had gone by, and, so far as the hands were concerned, they got quite well. The same appearance took place on the soles of the feet, and went through exactly the same course. The disease altogether, both in the hands and soles of the feet, did not occupy more than a fortnight, and then left the patient quite well.

I had another patient living in my own neighbourhood, who had a similar affection in the soles of the feet, which I could only call eczema, but which was of a more chronic kind; in fact, in this female the complaint lasted about four years. I first saw her about three quarters of a year ago; she then shewed me the soles of her feet, which exhibited a vesicular appearance; they were partly scabbed, from an encrusted state of the cuticle covering them. On the plantar aspect of the toes, along the borders, there were a number of vesicles, partly containing a watery and partly a somewhat yellow fluid. The soles of the feet and the toes were so tender, that she could not put her feet to the ground without pain. The complaint had then lasted about three years, and she had tried an immense number of applications; every thing of a strong kind, she said, disagreed with her, and did her harm. In the first place I directed the application of a poultice to the soles, that I might get the parts clean, and see something of their exact state. When the encrustations were removed by the poultice, the soles of the feet and the surface of the toes presented a curious appearance: the cuticle was perforated all over by a number of little openings, not unlike a number of shot holes. These were the openings of a number of vesicles, which had broken and discharged their contents. There was a great quantity of vesicles, containing a transparent or light yellow fluid, and the skin of the parts was of a bright red, highly inflamed. I directed her to apply a number of leeches and some soothing applications to the parts, adopting such internal remedies as this state of things seemed to require, and adhering to the rules of diet. When she put on the leeches the relief was so great that she thought she was cured. However, it soon turned out that she was not so; and, in fact, she is not well at this time, though it is about three quarters of a year since I first saw her. She has been in the habit, from time to time, of applying leeches and poultices to soften the cuticle; she has taken care of her diet, and paid attention to the state of her bowels; and, although she is not well, she suffers little compared with what she did before. She can move about the house, bearing the

weight of her body upon her feet, and is in a state of comparative ease and comfort.

Small-Pox and Cow-Pox.

I come next in order to *pustula*, or pustular diseases of the skin; and here, in the first instance, we come to *small pox*, *cow pox*, *chicken pox*. Now vaccination and inoculation are certainly surgical operations; but I think, if we may borrow a phrase from the nursery, these are the “early lessons” of surgery, and as I have no doubt but you have been initiated into them, I do not mean to describe the mode of proceeding in either vaccination or inoculation. I dare say you are acquainted with the appearance of vaccine vesicles, so that I need not enlarge on that point.

Cow pox and chicken pox are considered as belonging to the physician, and are treated of in medical lectures, so that I need not speak of them. It is, however, perhaps necessary for me to refer to the opinions that have been entertained respecting vaccination and inoculation—to the advantages which belong to the former, and the grounds that would lead us to prefer it.

Hitherto it was held that vaccination was a complete and effectual preservative against the occurrence of small pox; and, in fact, at one time it would have been deemed a very great heresy to have entertained a doubt upon this point. The doctrine was, that the effect of cow pox under all circumstances, and for any length of time, would protect the individual in whom the true vaccine disease had been produced, from all danger of the variolous disease. Now, I am old enough to remember the publication of Dr. Jenner's work, and the first introduction of vaccination. Some years after it had been introduced, a question was proposed to Dr. Fordyce, (a celebrated physician and lecturer in London, a man of great experience, and considered to have a very sound head,) by some one who met him at a coffee-house that he was in the habit of frequenting—for he was rather fond of port wine, “Pray, Doctor, give me your real opinion about vaccination; what do you think of it?” The Doctor replied, that he should be very happy to tell the individual his opinion upon it “fifty years hence;” and in point of fact, in speaking upon a question of this sort, it requires a long series of years before we can give any satisfactory answer on the subject. Now it was held, for instance, that the protection which vaccination afforded to the constitution against the small pox would be as perfect at the end of 50 years as it was at the very commencement of the period. I need not observe to you, that that is a point which could only be observed by experience, so that until the period have elapsed, we cannot tell whether it is to be so or not. I believe I may say the general opinion now is, that

the preservative influence of the vaccine disease gradually wears out; at all events we find that the number of instances of failure (if we may so call them)—that is, the number of instances in which small pox occurs in individuals who have been vaccinated, becomes greater in proportion as the time intervening between the vaccination and the period of attack increases. In order to elude this difficulty, the advocates of vaccination have said, that small pox inoculation is only an imperfect preservative against small pox; that it happens sometimes that persons have the small pox after inoculation, and that there is secondary small pox, as well as small pox occurring after vaccination. That there are such cases is certain; but they are not so common as the others. Now I am not much in the habit of seeing these cases; however it has happened to me to see instances where the small pox has occurred after vaccination; but I never saw an instance of secondary small pox. We must allow then, that although persons are not justified in saying that the preservative influence of cow pox extends only to a limited time, yet we may say that, so far as we know, the preservative influence becomes weaker in proportion to the length of time that elapses from the vaccination. In the majority of instances where small pox occurs in individuals who have been regularly vaccinated, we find that the disease pursues a different course from the natural small pox; we find that it is milder—that its duration is shorter—that, instead of running through the regular series of changes that belongs to the natural small pox, it will stop all of a sudden at a certain point, and come to a premature end. But this has not been invariably the case; there are instances in which small pox occurring after vaccination has gone regularly through its stages, and even ended fatally. Still all that I can say for myself is, that I shall continue to recommend and practise vaccination although it may not so effective, so invariable, and so never-failing a preservative against small pox as was heretofore considered. I shall do it for these reasons:—

First. The cow pox is a mild, and I might almost add, an insignificant complaint. Vaccination is attended with no danger, and hardly with any inconvenience, to the patient on whom it is practised; and that is generally on very young subjects. If, therefore, it should not be an effectual preservative, you may still adopt it, because there is so little inconvenience and risk attaching to it.

Secondly. In the great majority of cases, so far as experience goes, it is an effectual preservative against the small pox.

Thirdly. In the great majority of those instances in which small pox occurs after vaccination has been employed, it terminates favourably.

So that, for these reasons, I should recom-

mend vaccination to others, and practise it on children of my own.

The mention of small pox induces me just to draw your attention to a proposition made by the French, which I deem worthy of attention now, when cases of small pox are more frequent (perhaps in some measure, in consequence of an increasing want of faith in the cow pox) than they were some years ago. Some French writers have said that the application of lunar caustic to the variolous pustule in the early stage will prevent its development, cut it short, and prevent its proceeding to those unpleasant consequences which, particularly in the face, often lead to circumstances that are so afflicting to the individual. In the Archives Generales de Medicine, a French periodical work, Volume viii. there is a paper on this subject by M. Velpeau; it is entitled, "On the Employment of Caustic as a Mode of Arresting Variolous Eruption." It has been found by this gentleman, and others who have followed the plan he has pointed out, that if the lunar caustic be freely applied to the variolous pustules within the three first days (I may observe, that they do not deserve the name of pustules during this period of time, they are only pimples), however, making use of the term variolous pustule generally—if lunar caustic be applied within the three first days of the complaint, it will cut it short and prevent the progress of the pustules; and in the case of pustules that appear on the face, the eyelids, or other parts of the body that are uncovered, this plan may be adopted, so as to prevent their progress to those changes which are so disagreeable from the deformity which they leave. In some instances this method does not seem materially to interfere with the progress of the affection, but in others it abridges it, interrupts the regular course, makes it shorter, and in no instance in which it has been employed for this purpose has it been attended with any unfavourable effect. The progress of the pimples or vesicles, when the caustic is applied in the early stage, is completely stopped, and a small darken crustation is formed upon their summit. M. Velpeau observes that it is a curious and interesting sight to notice the difference between the pustules that are thus cauterized and those that are allowed to proceed through their natural progress; that while the latter go on to a state of full suppuration, and exhibit very large hemispherical prominences, with high inflammation of the base, the former shrink and disappear, and exhibit only a small superficial encrustation, just the effect of the application of the caustic, without any inflammation of the base of the pustule. The consequence of this sudden interruption of the progress of the local affection is, that the inflammation at the base is put a stop to, which is very important in re-

ference to the pustules that are formed upon the face.

Now, there was a woman lately under my care in this hospital with the small pox. I had the pustules on the face cauterized; but afterwards it turned out that this was a case of secondary small pox—that is, the individual had been vaccinated in whom at a certain time the variolous disease was cut short, so that I could not see the effect of the caustic, but it appeared to be according to the statement of M. Velpeau.

The modes of application that he speaks of are these; either to have a pin of silver or of gold, sharp pointed, and to dip it into a concentrated solution of lunar caustic, and with the pin to pierce the minute vesicles that may be formed on the summit of the variolous elevations, so that the solution may be applied to the interior of the vesicle—to cut off with a pair of sharp curved scissors the prominent part of the vesicle, and cauterize it with the nitrate of silver brought to a fine point; or, simply to take a portion of the nitrate of silver to wet the surface of the variolous elevations, and rub it over externally. These are the means adopted, and they are very simple.

Now, if this principle is applicable to the treatment of variolous pustules, no doubt it will be applicable to many other states or affections of the skin; and, indeed, M. Velpeau mentions that in the first instance he tried the plan on boils. Taking individuals in whom these were coming, he freely cauterized the swellings, and in some of them nothing but a minute elevation appeared; so that the free application of lunar caustic to these places suspended the inflammation of the boil, and occasioned it to diminish and finally to disappear.

At the same time that these proceedings with the lunar caustic were being carried on in France, an English surgeon made some experiments with it in a variety of affections. The gentleman to whom I allude is Mr. Higginbottom, of Nottingham, who published an essay on the effect of nitrate of silver in several complaints. He has lately published a second edition.

Mr. Higginbottom has employed the free application of the nitrate of silver, moistening the surface of the skin, and then rubbing it over with caustic, in phlegmonous erysipelas, whitlow, in erysipelas of the face, in inflammation of the absorbents, and in various local affections; and, as he states, with the most beneficial results. We should not, perhaps, *à priori*, have entertained the idea of rubbing over the inflamed surface of the face with lunar caustic, and turning the face of that black colour which we know that nitrate of silver will produce on the skin; but experience is the only test for these and all other matters of a similar nature; and although things may appear at

variance with general principles and received notions, if we find them hold good when we have tried them, we shall no doubt be able to reduce them to principles when we have investigated them, or we shall find that those principles, or supposed principles, which have been laid down, may require correction. The free application of lunar caustic to the face, in erysipelas, has been found to have the best effects in arresting and controlling the complaint. I remember seeing a case where there was excessive inflammation of the absorbents up the leg and thigh (I forget exactly from what local cause it arose), and in which the nitrate of silver had been freely employed upon the limb in the course of the inflamed absorbents; and, as far as I saw, with the most decided effects in putting a stop to the inflammatory action. The treatment appeared to me more beneficial than I should have supposed any other would have been, under such circumstances.

Then Mr. Higginbottom also speaks of the employment of nitrate of silver in other cases—to punctured wounds, bruises, leech-bites, wounds received in dissection, &c. In all these instances he applied lunar caustic freely, leaving the parts subsequently exposed to the air, to produce what he calls an *adherent eschar*. We find generally, in cases of wound, a kind of crust forms over it, to protect it from the air, and that it heals underneath; and the employment of lunar caustic, by Mr. Higginbottom, seems to be intended to assist in producing this external covering to those wounds, and thus to give an opportunity for the healing process under it. In small ulcers he has attempted to produce an external eschar in the same way; and there are a variety of cases in which he has used it with success. I cannot exactly say that I have read the second edition of Mr. Higginbottom's work; but I have read the first. It contained numerous hints worthy of attention; and I think you will find the second edition worthy of perusal, as giving a number of details respecting the employment of this powerful agent, in a way and under circumstances in which it has not hitherto been made use of.

LECTURE XXXVII.

Ecthyma—Rupia—Impetigo—Acne—Lepra—Psoriasis—Strophulus—Lichen—Prurigo.

The term *ecthyma*, gentlemen, designates a pustular eruption, consisting of large pustules with inflamed, bright-red, and indurated bases. They are single, scattered over various parts of the body, not collected together in groups. They seem to form a kind of intermediate link between some other pustules, in which there is a more su-

perforated inflammation of the skin and boils; in which there is a deeper-seated inflammation, with sloughing of the cellular membrane. This form of eruption is sometimes seen mixed with some of the forms of syphilitic eruption, but more commonly it occurs as a consequence of a disturbed state of the digestive organs, or in constitutions that are debilitated either by long-continued disturbance of those organs or by any other causes.

Rupia.

The affection which has been called *rupia*, is in some measure analogous to ecthyma, inasmuch as it occurs either from syphilitic affections or in individuals of debilitated constitution. It is not, however, a pustular disease; in fact, it commences as a vesicular affection; there is a large and flattened vesicle, and the surface occupied by this subsequently forms an ulcer, which is usually of a circular figure. Now *rupia* is classed, by Dr. Bateman, among the vesicular affections of the skin, while, on account of the size of the vesicle, Rayer classes it among the bullæ—the bladders. When the vesicle has ulcerated, the discharge which is produced from the ulcerated part encrusts, and forms a yellow scab upon the surface. When the ulceration increases very rapidly, this scab assumes a peculiar form; for, in proportion as successive crusts are added to the surface of the ulceration, the scab enlarges at the base, in consequence of a fresh kind of deposition taking place. Thus the scab at last assumes a conical shape; the portion which existed originally forming the apex of the cone, and the base being formed by the layer last deposited. This difference has occasioned names to be given to the particular forms, as if they were distinct species—thus there is *rupia simplex* and *rupia prominens*, or that in which this conical projecting scab is formed. I think you seldom see *rupia* except in individuals who have had syphilis; I regard it, therefore, as a syphilitic symptom generally.

Impetigo.

The term *impetigo* is given to an affection consisting of clusters of small pustules and inflamed patches of the skin. These are attended with a great deal of redness and itching, acquire a certain magnitude, break and discharge their contents, which form in thin yellow scabs on the surface of the part. These fall off, and leave the surface of the skin which they had previously covered of a bright red colour, itchy and sore, usually cracking or chapping from slight causes. You have a succession of these groups of pustules forming on various parts; and the affection sometimes becomes disseminated nearly over the whole of the surface of the body.

The causes of *impetigo* are, generally speaking, internal; but occasionally this affection is produced by obvious external irritation. Now the affections which take place in the hands of grocers, bricklayers, and washerwomen, are sometimes of this pustular character. Pustules are produced, as you well know, by the immediate local irritation of tartar emetic ointment; and groups of pustules or small boils, frequently form from the local irritation of blisters. Pustules, either singly or in groups, are frequently produced by the local irritation of poultices. Thus, when poultices are made of improper materials—as of bread which is sour, or of other substances in an acrid or rancid state—very often considerable inflammation of the skin is produced by their local use, and a pustular eruption occurs in consequence of it, which is very annoying to the patient, and often tedious to cure.

Acne.

The term *acne* is employed by later writers on the diseases of the skin, to denote a tubercular inflammation of the skin, proceeding to suppuration, occurring on the forehead, the face, the neck, and the upper part of the chest. This is the affection which the French call *couperosé*. The nosologists have adapted the name to the part in which it appears. Thus the French writers call it *visage couperosé*, just as we speak in common language of having a carbuncled face. In this eruption, then, of *acne*, there is inflammation with tubercular elevations of the skin, which are of a chronic kind. After some time, these proceed to imperfect suppuration. They break, discharge, and then crusts form upon them; the tubercular elevations of the skin subside, leaving, however, marks or eschars. Several of these form, generally single, but sometimes in small groups, on the skin of some part of the face or forehead, more particularly in females; sometimes upon the neck and upon the upper part of the chest, and, unluckily, just so far down as ladies are wont to expose their persons: they seldom extend below the part where the dress begins to cover the neck. Intermixed with these elevations, there is frequently a morbid state of the sebaceous glands: about the face, and the other parts affected with the eruption, you see little black points, which, in fact, are the obstructed orifices of the sebaceous glands of the skin, intermixed with these tubercles of *acne*. Now you have a succession of these tubercles—that is, while some are suppurating and declining, others are forming; and thus they may go on for a series of years, keeping up this unpleasant appearance by their successive production.

In some instances these tubercles do not proceed to suppuration; ordinarily they are

chronic in their course—they do not quite suppurate. But in some instances they seem to retain their tubercular character, and form elevated indurations of the skin, disfiguring the countenance excessively.

By the term *acne simplex* is meant the tubercular elevations generally proceeding to suppuration. By the term *acne punctata* are designated those black specks which sometimes appear simply as the result of obstruction of the sebaceous glands; sometimes they lead to inflammation of the follicles connected with them, and to suppuration of the parts.

The term *acne indurata* denotes that form of the affection in which the tubercles do not proceed to suppuration.

Acne rosacea, the rose acne, is applied to that form of inflammation of the integuments of the nose which occurs in persons who indulge in eating and drinking; in fact, who are free livers. It consists of an inflammation of the integuments of the *alæ nasi*, and of the nose generally. The parts usually assume a bright red colour, become granulated at the margins and surface, and rise into large tubercular elevations, such as have been already described; and these proceed to suppuration, break, and form encrustations. In the first instance, that is, when this appearance first shews itself, the skin of the *alæ nasi* is of a bright red, almost of a fiery red. These constitute what is called a carbuncular nose; and although this is an affection which remains often during the life of the individual, the part assumes the same bright fiery red colour, with a sensation of heat and itching on mere exposure to the fire, or on taking spirits, or any article of food which excites the stomach considerably. At other times the part assumes a more livid hue; and in process of time the neighbouring skin, and this granulated part of the integument, also display a considerable number of livid and almost varicose ramifications of the capillaries. As the cause which produces this effect generally continues to be applied constantly, so the skin of the nose is maintained habitually in this state of inflammation. You have a succession of pustules, which break and encrust, and so they go on from year to year, often considerably thickening the integuments of the nose, and occasioning considerable enlargement of the glandular textures; in fact, there is a considerable augmentation of bulk in the organ generally, which must be chiefly referred to the capillaries in the skin enlarging, and thus increasing the glands, and thickening the cellular texture under the skin. Now when this is commenced in early life, and the causes that have produced it have been continually applied for a long series of years, very extraordinary growths are sometimes produced in this affection, constituting lobular appendages,

by which the organ is prodigiously increased in magnitude, sometimes with great inconvenience, so far as the passage of air through the nose is concerned, and even interfering with the motions of the lips in the taking food. In this enlarged state of the integuments of the nose, (and which has sometimes been called carcinomatous enlargement of the nose, or carcinomatous tumor, although there is nothing of cancer in the affection) you may safely employ the knife to extirpate the growth. It is simply enlargement of the sebaceous follicles and integuments. It is an enlargement of parts not important in themselves, and which, if not in a state of active inflammation at the time, may be freely dealt with by operation. I have seen several instances where considerable growths have been thus removed. You must endeavour to carve the nose so as to leave it of a tolerably good shape. The wound thus produced will generally heal favourably, and you rid a person of that which is not only very troublesome but which is a very conspicuous deformity, by such an operation.

The affections which constitute what are commonly called *tinea capitis*, *porrigo*, or scald head, are of the pustular kind, but as I shall have occasion to speak of them separately, I shall say nothing about them at present.

Lepra.

The *scaly* diseases of the skin are referred to three heads. In the first place, that which is called *pityriasis*, which is a very slight scurfy affection of the skin, generally occurring on the head of the new-born infant—the *pityriasis capitis*, or dandriff, a very slight affection. *Lepra* and *psoriasis* are the two other heads.

Lepra consists generally of circular patches of chronic inflammation of the skin, the borders of which are elevated, tubercular, and red, the centre being comparatively depressed. In those patches, which in the first place appear simply as a thickened inflammation of the skin, the cuticle, after a time, begins to separate in small portions, assuming a scurfy and scaly state, and afterwards scaly encrustations form upon them, sometimes to a very considerable thickness; sometimes they assume a bright shining appearance, at others they are of a dark colour. They generally come upon the knees and legs, and on the elbow and the forearm and arm. These are the common situations, but occasionally they spread extensively over various parts of the body; and there are individuals in whom such leprous patches continue through a considerable part of life; sometimes they are troublesome, being attended with heat, itching, and uneasi-

ness; at other times they are in a comparatively quiet state.

Psoriasis.

Psoriasis, which is another form of scaly disease, differs from *lepra*, although they approach to each other, and we find it difficult to make out the boundary between them. *Psoriasis*, however, affects the skin in patches of an irregular figure, not circular, but quite irregular. It has not the elevated border of *lepra*. The cuticle becomes thickened, cracks, and goes into a fissured state, and a slight thin kind of encrustation is thus formed upon the surface of the part. This is usually detached, for it does not adhere so firmly as in *lepra*, and it leaves a red and sore state of the integuments under it, a state in which the skin easily fissures or cracks, and in which the ordinary motion of the part forms such cracks, so that you have not simply the common irritated state of the skin with encrustation adhering to it, but also fissures and chaps proceeding to a considerable depth, and producing considerable pain.

There is one form of *psoriasis* which cutaneous nosologists call *guttata*. This is first seen in small dots over the skin, seldom exceeding the diameter of two lines; it approaches a good deal to *lepra*, and forms a kind of connecting link between the two affections. Now *psoriasis* seems, in many instances, to be produced by local causes, for it will affect certain parts of the body without extending to others. There is *psoriasis labialis*, in which the state that I have described affects the lips. Then there is *psoriasis præputii*, affecting the prepuce in male subjects. There is also *psoriasis palmaria*, affecting the palms of the hands. This is sometimes extremely troublesome, as it frequently takes place in individuals whose usual occupations are attended with some particular pressure or irritation of the palm of the hand, and thence arises the affection; in other instances, it takes place in persons who do not follow mechanical operations of that kind, and in whom we cannot trace any local causes. The skin, in such instances, becomes inflamed in patches; the thick cuticle cracks and fissures, becomes dry, harsh, and uncomfortable. The cutis under it also cracks, and particles of dirt or other substances finding access, produce considerable uneasiness. This is a form of the affection not uncommonly seen in washerwomen, in consequence of the soap and alkalies which they use; the alkaline substances which they use in cleansing the linen habitually increasing eruptions of this kind.

Lichen.

The *papular* diseases of the skin consist of elevations of the surface of the skin, which

are solid; there is no effusion of lymphatic fluid, nor of pus, but the elevations are either red and inflamed, or of the same colour with the natural skin, and they are particularly distinguished by the very troublesome itching which accompanies them; in fact, itching seems to be the particular modification of pain which accompanies disease affecting immediately the skin itself; and in all those affections in which the proper texture of the cutis vera, or true skin, is engaged, you generally find more or less of that peculiar degree or form of sensation called itching. Those elevations of the skin which constitute papulæ, generally end in resolution, that is, they disappear, they go away entirely, or end in slight desquamation; and sometimes an affection, which is originally papular, may form small vesicles or pustules before it disappears.

You read sometimes of the term *strophulus*, or red gum, as given to an affection of this kind in children, arising from a variety of causes, as dentition, derangement of the digestive organs, and so forth.

The term *lichen* is given to an eruption of inflamed papulæ occurring in particular parts of the body, or extending more or less generally over the whole surface in young persons or adults, and attended, in many cases, with an almost constant and intolerable itching. The patient itches to such a degree that he scratches the skin with his nails, or rubs it with brushes, or even tears it with combs, to get some relief from the annoyance which the itching produces. This is frequently produced by external heat, and hence it is found to be an affection exceedingly troublesome to those Europeans who have visited tropical countries.

Lichen tropicus is the name given to an affection of this kind, which sometimes occurs in persons visiting the East and West Indies; the eruption produced by the heat of those countries is often called the *prickly heat*: it is attended with an itching, the most severe and intolerable that can possibly be conceived.

Prurigo.

Prurigo, as the name imports, is an eruption attended with excessive itching, for that, in fact, is the meaning of the term, but the papulæ, or pimples, are of the natural colour of the skin; they are not red, as in *lichen*. They may extend generally over the body, or be confined to a particular part. Sometimes it is milder, sometimes more severe. There are several varieties of this affection. There is *prurigo mitis*, and *prurigo formicans*. It often exists in elderly persons, constituting the *prurigo senilis* of Dr. Willan. Sometimes it affects particular regions of the body, as the anus, for example, constituting *prurigo podicis*; or the entrance of the

female organs of generation, when it is called *prurigo pudendi muliebris*.

Now I do not consider it necessary, nor, in fact, would it be attended with any advantage, were I to enter into a lengthened description of the complaints of the skin that I have just mentioned generally, unless we had an opportunity of pointing them out in patients, and shewing their differences; it would be quite tedious to go over all the various species which nosologists have distinguished. You will be immediately aware, that in their essential nature there is no great difference among these, although they are distinguished by different names; in fact, in these various affections of the skin, we see only different modifications and different results or effects of inflammation. We see either the simplest kind of inflammation, consisting merely in vascular distention—efflorescence; or a higher degree, in which there are papular inflammations and elevations of the skin; or a still higher degree, in which there is the formation of vesicles; or a yet more advanced degree, in which there is the formation of pustules; or other kinds of affection, in which there is the formation of scales—the scaly diseases of the skin; but yet the essence of each of these is similar.

Now these inflammations of the skin, like inflammations in other parts of the body, may be acute or chronic—that is, you may have active vascular distention, increased redness, considerable pain, heat and itching of a part; and you may have sympathetic effects produced on other parts of the economy, corresponding to these—that is, where there are considerable portions of the skin affected, you have excitement of the vascular system and of the digestive organs. In other instances the local affections, and general sympathetic influences, are less considerable; these are chronic affections of the skin.

The causes of these different inflammations of the skin are very various. In a great number of instances we see them produced directly as the immediate effect of local irritants upon the skin. This is evidenced in the pustules and superficial sloughs caused by the application of tartar emetic ointment; by the effect of direct solar heat—*eczema solare*; by the effect of mercury applied to the skin—*eczema mercuriale*; by the groups of pustules seen in *ecthyma*; by boils and carbuncles; by the effects produced by the irritation of blisters, setons, and various other applications, to the skin; and by the scaly, or pustular, or vesicular affections, which constitute the grocers' itch, or the bricklayers' itch, and the complaints affecting the hands and wrists of washerwomen. In other instances we see that the complaints of the skin are produced by direct applications to the body of some morbid secretion,

or of contagion in some shape, as in itch, and in the exanthemata properly so called—that is, measles and scarlet fever, small pox, cow pox, and chicken pox. In other instances affections of the skin are the consequences of poison introduced into the system, as in syphilis; and here you observe that the poison, if we should deem it such, is capable of producing almost all the forms of cutaneous affection; it will produce pimples, tubercles, scaly eruptions, pustules, and ulcerations. In some instances we see affections of the skin obviously produced by disturbance of the digestive organs, as urticaria, or nettle rash, in various parts of the body; the acne rosacea, certain forms of psoriasis, and various other diseases of the skin, are obviously produced by that cause. Still a great number of affections of the skin remain, in which we are unable to point out the direct exciting causes; and these must be produced by some internal cause, the exact nature and mode of operation of which are hitherto not accurately ascertained.

[This concludes the history of cutaneous diseases. We shall give the treatment in our next number, so that the subject will be continued at page 161—opposite.]

LITERARY ANNOUNCEMENTS.

Dr. A. P. W. Philip has in the press, a Treatise on the Nature and Cure of those Diseases, whether Acute or Chronic, which precede Change of Structure; with a View to the Preservation of Health, and particularly the Prevention of Chronic Diseases. In 1 Vol. 8vo.

Dr. Ure has in the press, a New Edition, nearly re-written, of his Dictionary of Chemistry.

NOTICES.

The case of Hernia, from Brighton, does not appear to present any circumstance of sufficient interest for publication. Any more interesting cases we shall be extremely glad to have.

"T." was accidentally omitted last week; we shall attend to it hereafter.

"Veritas," of Manchester, is informed that we cannot possibly contradict, on anonymous authority, a statement bearing the writer's name.

"Norfolciensis."—We shall inquire.

"A Constant Non-Medical Reader."—Various cases of pytalism, from crude mercury, are on record. We have ourselves seen it, where the quicksilver was used empirically for rheumatism, in drachm doses, every night for three weeks.

LECTURES ON SURGERY,

Delivered at St. Bartholomew's Hospital,

By WILLIAM LAWRENCE, F.R.S.

LECTURE XXXVII.

[Concluded from the preceding page.]

General Observations on the Treatment of Cutaneous Diseases.

THE treatment of acute inflammations of the skin must be like the treatment of acute inflammation situated in any other texture of the body. You must employ antiphlogistic means. Occasionally you find it necessary to take blood by venesection, and in many instances to apply leeches to the affected part; and here I may observe, that you need be under no apprehension of the local effect of the leech-bites on the part that is the immediate seat of inflammation. In these cases, the same observations which I made respecting the application of leeches to parts affected with erysipelas, are equally true as regards leech-bites in other affections of the skin. With these means you combine the other parts of antiphlogistic treatment; that is, perhaps, pretty active purging and low diet; at all events, you take care that the patient shall exclude from his diet all stimulating articles, whether of a solid or a liquid kind. In conjunction with these general means, in cases that require that kind of treatment, you employ local measures of a soothing nature, such as are calculated to reduce the inflammation. Hence you apply sometimes cold washes to the inflamed part, such as saturnine lotion; or spirituous lotions with vinegar—2 ounces of vinegar to 8 ounces of the lotion. This is a form which is sometimes not only calculated to lessen, and thus to check inflammation generally, but also to alleviate the itching, which frequently is very troublesome in these cases. Tepid ablution, fomentations, the general warm bath, or rather, I should say, the tepid

bath, are occasionally useful. There are instances in which the cold-bath is advantageous; for instance, where the troublesome itching would be aggravated by warm applications. Soft poultices, mild unctuous applications, the ceratum cetacei, elder-flower ointment, or that mild kind of preparation made by perfumers, called cold cream—these are the mild soothing applications which are proper in inflammation of the skin in the active stage, in which it is found necessary to employ antiphlogistic treatment.

In chronic inflammation of the skin you employ a similar kind of treatment in a milder way. It is sometimes advisable to take blood generally even in what we call chronic inflammation of the skin; for we frequently find a state of great plethora keeping up the disease;—and you combine with this the pretty active use of aperient medicines—calomel, the extract of colocynth, and other forms that I have already spoken of. You may occasionally employ leeches to the inflamed parts with advantage even in chronic affections of the skin. More generally, however, you find that in chronic inflammation of the skin it is sufficient to regulate the digestive organs, and to pay attention to diet. In saying this, I do not mean that you are to purge every patient that has inflammation of the skin actively, or to put every patient upon low diet. It is sufficient to pay attention so as to exclude from the diet exciting or stimulating articles; generally speaking, patients should take fermented liquors sparingly under such circumstances, and a smaller quantity of animal food than what they take in a state of health. They should take what is called light diet—farinaceous articles, with a moderate portion of animal food. In the same way you must pay attention to the bowels. Though patients require sometimes the active exhibition of purgatives, they will usually require only mild alteratives and mild aperients. You will understand, however, that all cases of affection of the skin are by no means to be cured by attention to the state of the digestive organs alone. This is a point that is

always of importance to be attended to ; it must never be neglected. But there are numerous cases of serious diseases of the skin in which the stomach and digestive organs are in their natural state ; and there are many instances in which they continue so throughout the complaint, and yet the diseases of the skin go on in the same way. We are by no means to understand that active purging is always necessary, and that attention to the digestive organs will always cure the disease, and still less will it always be advantageous to employ mercury in such cases ; in fact, in chronic inflammation of the skin, when we have regulated the state of the digestive organs, and put the patient on a proper diet, we find it necessary to pay attention to the local treatment of the case, as local means are capable of doing a great deal, particularly in instances where there is much itching and irritation of the skin. I have already mentioned that the application of acetic acid, in the form in which it is found in common vinegar, is sometimes of use. Now it has been found advantageous to employ this remedy in a stronger form than that in which it exists in common vinegar. Mr. Wilkinson, who has written a small but sensible pamphlet on cutaneous diseases, attending more to the general principles which are to be observed in their treatment than to the minute distinctions of all the various shades of these diseases, recommends acetic acid in a strong form, as an occasional application to the skin where the itching is exceedingly troublesome. I think he employs the aromatic vinegar, which is merely the concentrated acid, mixed with about one-half of rose-water. When you employ it in this way, you must have the surface cleansed, and merely dab it over with the acid. The acetic acid, in its strong form, is capable of acting as a powerful escharotic. Dr. A. T. Thomson, who has edited recently an edition of Dr. Bateman's Synopsis of Cutaneous Diseases, has recommended the hydrocyanic or prussic acid, in the proportion of one or two drachms to about eight ounces of emulsion of bitter almonds, or in other forms, to be employed in the same way to the surface of the body, as means of alleviating the troublesome itching. Then, in all cases of chronic cutaneous affections, cleanliness, frequent ablutions, and the employment of the warm-bath, are of very great importance. Carefully cleansing the surface is essential, because it affords us the means of examining and applying whatever active substances we may use to the part that is diseased ; and the warm-bath has the further beneficial effect of maintaining an active state of the capillary circulation in the skin generally. It is thus calculated to correct, in the parts particularly affected, the local excitement which prevails in them. We may say there-

fore generally, without adverting to particular diseases, that a frequent use of the warm-bath is a very powerful auxiliary, whatever other plan of treatment we may deem it advisable to adopt.

We find it necessary, when these affections go into a chronic state, to employ means locally, which are of an exciting or stimulating character ; and thus we are enabled to produce changes in the condition of the skin, in instances where the disease has lasted for some time—where deposition has taken place into the texture of the skin, and where there is an incipient change in the structure of the parts. Thus in the indurated stage of acne, where we can do no good by antiphlogistic treatment, or other means of that kind, the red precipitate ointment, in a mild form, (ten or fifteen grains to half an ounce of lard, made into an ointment), may be employed advantageously, rubbing it once or twice a-day upon the affected parts. Rayer, and some other foreign writers, have recommended strongly an ointment containing a considerable proportion of calomel, particularly in scaly affections of the skin ; but I have not seen it employed. He recommends a scruple of calomel to an ounce and a half of lard, to be rubbed on the part. By this application, Rayer says that he has succeeded in arresting various affections, where the application of other means had failed. The oxymuriate of mercury, in solution, is a powerful local application in these cases ; and perhaps it is most efficacious when it is used in solution, in conjunction with alcohol. Thus, in eight ounces, there may be two ounces of alcohol ; and you may employ from one to two grains of oxymuriate of mercury to the ounce, beginning with the smaller quantity and gradually increasing it, and applying it to the affected parts once or twice a-day, or more frequently. This is considered to be the base of a quack medicine which has attained great celebrity, under the name of *Gowland's lotion*. The oxymuriate of mercury is there used in conjunction with emulsion of bitter almonds. The oxymuriate of mercury, dissolved in strong acetic acid, has been found a useful application in some obstinate forms of psoriasis. When psoriasis affects the palm of the hand, it sometimes extends to the nails, which become altered in colour ; they split, and become incurved at the end ; they assume altogether an unnatural appearance, in consequence of inflammation of the part which produces them ; the unhealthy nail separates, and another as bad succeeds it. The oxymuriate of mercury, in the proportion of one, two, or more grains to the ounce of acetic acid, has been employed efficaciously in this form of psoriasis. I have seen it stated, that some cases of psoriasis, affecting the palm of the hand, have been

efficaciously treated by the application of concentrated nitric acid to the part. This is only to be employed very carefully. You must first soak the surface, and then, after drying it, you must lightly and superficially apply the acid to the part with a piece of lint wrapped round a probe dipped into the acid. It has been said that the morbid cuticle is thus thrown off, and a healthy skin produced, in consequence of such application. I have not seen it used myself. There is a strong local application of this kind occasionally employed by the French, in some obstinate cutaneous diseases, of the immediate effect of which I am not able to speak. It is the nitrate of mercury. It is used in the Hospital Salpetriere, in Paris, where a great number of cutaneous affections are constantly under treatment. It is made by dissolving a drachm of red precipitate in an ounce of nitric acid, and is to be employed in the way I have just mentioned; that is, superficially, just applied on the surface of the part, unless you want to employ it as an escharotic, to destroy the surface, when of course you may use it more freely, in order to produce a slough of the part. Sulphur, as a local remedy, has been generally considered to possess considerable power in the treatment of diseases of the skin. Thus the natural sulphureous waters in various countries have become celebrated in the treatment of these diseases. The Harrowgate waters of this country certainly, in many cases, produce beneficial effects where, perhaps, our regular treatment has failed. The hydro sulphuret of potash may be employed, dissolved in water, and should be used in solution, in the proportion of one or two drachms to a pint of water, in cases where we cannot give the patient the advantage of the employment of natural sulphureous waters. The sulphur ointment may be employed for the same purpose, and sulphur may be also used in vapour, as in the sulphureous vapour bath. Tar is another remedy that is considered efficacious in diseases of the skin. Frequently tar, with sulphur ointment, are combined together in equal proportions. The citrine ointment is also used. Sometimes tar and citrine ointment are mixed together. We are obliged frequently to alter the applications, as they lose their effect when repeated for a considerable time. The nitrate of silver, either in solution or in substance, is another local application of considerable power.

I should have mentioned to you, with respect to the internal treatment in these cases of chronic cutaneous affections, that occasionally there are obvious signs of disturbance in the stomach from acidity, a defect in the digestive process, under which the internal exhibition of alkalis is of considerable

advantage. It is seen occasionally in cases of the acné; it is also seen in cases of psoriasis. Here the liquor potassæ may be given internally, but in rather larger doses than it is commonly employed; a drachm, for instance, and from that to a drachm and a half, three times a-day. Dr. Thomson recommends the exhibition of it in emulsion of bitter almonds, as a vehicle, or that it be given in combination with a tonic, such as infusion of cascarrilla. In some cases, particularly of scaly affections of the skin, which have existed for a considerable time, and resisted other means of treatment, arsenic may be employed internally with advantage—the liq. arsenicalis of the London Pharmacopœia being the form generally used. We cannot explain how this acts. We see in some cases, of lepra particularly, that it is beneficial, and hence it is given empirically. I need not observe to you that it is necessary to employ this remedy with caution; that it is capable, when used for a length of time—and these cases do not get well quickly—of producing serious effects on the animal economy. Its exhibition should be carefully watched; you should begin with very small doses, three or four drops two or three times a-day, cautiously increased. This remedy, however, internally, and a solution of oxy muriate of mercury in distilled water externally, seem to possess a considerable and peculiar power in certain chronic affections of the skin.

Now there are instances in which in some affections of the skin the patient is debilitated and enfeebled, and in which nothing like antiphlogistic treatment can be properly had recourse to—where we find it necessary, perhaps, to give the patient rather a good diet than otherwise, and to employ tonics, as mineral acids, and vegetable bitters, such as bark and sarsaparilla. In fact, in the treatment of affections of the skin you must be aware that, as in other diseases, you cannot lay down one, two, or three invariable rules; you must direct both the general and local treatment according to the condition of the patient, and the time that you employ them.

In concluding these general remarks on diseases of the skin, I beg again to advert to a point that I have already spoken of—the great advantages, under all circumstances, of attending to keeping the skin clean by the assiduous use of tepid ablutions, or the warm bath.

LECTURE XXXVIII.

Tinea Capitis—Porrigo—Elephantiasis—Lupus.

GENTLEMEN,—The terms *Tinea* and *Porrigo* are employed, technically, to designate the

same affections of the hairy scalp which are popularly called *scald head*, and sometimes *ringworm* of the scalp. *Porrigo* is the term employed by Drs. Willan and Bateman, and hence it has been generally adopted as the scientific name of these affections. The English term of "scald head" does not indicate any notion of the affection being connected with the operation of heat, or being at all the effect of scalding; but it is a term derived from an old English word, and means scab or encrustation—so that scald head in this sense means scabby, or encrusted head. The term *ringworm*, I believe, was originally applied to a particular form of eruption, which I have already had occasion to mention under the name of *herpes*—which is a vesicular eruption. In one of its forms the vesicles assume a circular arrangement, the interior of the circle being imperfect. It is called *herpes circinatus*, and the vesicles, when thus arranged, have the appearance of rings—hence the name *ringworm* given to the affection in common language. In one form of psoriasis, also, the inflamed and scaly state of the skin resembles a narrowish line, which usually assumes an imperfect spiral form; it has been sometimes called *ringworm* in common language; but the *ringworm* of the scalp is a certain form of the affection that I am now going to describe to you, in which the inflamed and pustular part exists in circular patches.

Now under the term of *porrigo*, Drs. Willan and Bateman include some other affections of the hairy scalp besides those to which the familiar name of scald head is applicable. They include some other affections which, in fact, have very little resemblance in their nature with scald head; and probably when these affections have been more minutely investigated, some of the complaints which they include under that term will be separated from the head of *porrigo*.

Porrigo, or *tinea capitis*, is an inflammation of the hairy scalp generally, commencing in patches, in which you see the formation of groups of minute pustules—pustules which are seated in the substance of the skin of the scalp. Now these pustules generally assume a peculiar appearance—they are very small in size, and produce a peculiar kind of secretion: they are such pustules as nosologists have distinguished by the term *achores* and *favi*. By the term *achor* (of which *achores* is the plural) a pustule is designated which is circular, minute in point of size, imbedded in the skin, and which produces a thick, and at the same time nearly transparent secretion, which has been compared to honey, which, when it exudes from the pustule, encrusts in a clear but firm kind of scab. The term *favus* is applied to a pustular affection of the scalp,

which is larger in extent, but produces a similar kind of secretion—a secretion similar in its sensible characters, and resembling it also in the circumstance of forming a firm yellowish crust.

The secretion which takes place from the groups of pustules which constitute the state of *porrigo*, forms in the first instance thin scabs, varying in size and in figure. In proportion as the disease proceeds, the continued exudation from these pustules adds to the thickness of such encrustation, and thus you have them enlarged in size, so that they become considerably elevated above the surface of the skin. These affections, if they are not well attended to, go on for several years, and thus you frequently see an individual whose head is covered over with bumps of encrustation—you have the masses of encrusted secretion rising considerably above the surface, and presenting altogether a very strange appearance. In some instances the scabs which form on these pustules have a depression upon their surface—a cup-like indentation. When they have increased in size and form, the elevated masses that I have just mentioned have been compared to various objects, and thus different names have been given to different forms of the complaint, derived from the appearance which the encrustation exhibits. Where there is a number of these encrustations with the cup-like indentation on the surface, they have been compared to the appearance of honeycomb: hence the name *porrigo favosa*—honeycomb scall. Sometimes it is said they are like the seeds of the lupine, and the affection has been called *porrigo lupinosa*. There are other instances in which, without rising so high, the encrustation forms circular scabs, and this constitutes the species termed *porrigo scutulata*. Now I do not apprehend that these various names indicate any essential difference in the nature of the disease—they are merely terms applied to modifications of form.

In the first instance the pustules appear to form on the scalp, in the intervals of the hair; but as the disease proceeds, the bulbs of the hair become involved, and are destroyed by the ulcerative process; so that when the complaint has existed for a length of time, and you come to loosen and separate from the head this long existing and firm encrustation of the scab which I have just described, you will find that a great proportion of the bulbs of the hair are destroyed, and, in fact, that the hair never grows again in that situation. When the disease has existed for a length of time, you find sometimes, even in young subjects, that the hair is completely destroyed, and that the scalp is left ultimately, if you succeed in curing the complaint, just as it is in the head of an old person who has

lost all his hair—the hair is entirely removed by the complaint.

The progress of this affection is of course much favoured by the neglect of cleanliness. Thus you find that some of the worst cases occur in children of the middling and lower classes, the latter particularly, where a proper attention is not paid to cleanliness; and frequently the disease which is produced on the scalp is materially aggravated by the additional irritation caused by numerous vermin—for they seem to breed and propagate most excellently in this state of the scalp.

It frequently happens that in this disease the lymphatic glands, through which the absorbent vessels of the scalp pass, become enlarged. Thus you have enlargement of the lymphatic glands seated behind the ear and along the neck.

This affection generally commences in, and is confined to, the hairy scalp; but it may extend from this to the neighbouring skin, and, in fact, over the whole body; so that you frequently find the same kind of appearance over the body which characterizes this disease when it is seated on the scalp—at all events the appearance is somewhat similar in its nature. It is said that this propagation of the disease over the body is produced by a kind of inoculation; that the patient scratches his head, which is the original seat of the disease, and having the matter on his nails, and applying them to other parts of the body, he inoculates those parts. But whether it arises in this way, or from other causes, it is not easy to determine.

Porrigio is considered to be a contagious complaint—that the matter which is secreted by the pustules of the inflamed scalp, applied to that of a sound person, is capable of producing the disease; and thus it is found very often, that a child affected with this complaint going into a school will communicate the disease to many others, and that, in fact, often under such circumstances the disease will run through all the inmates of the establishment. I believe it is not ascertained that all forms of the disease possess this contagious property; it is, however, generally agreed, that that form which is called porrigio scutulata, in which there is a circular portion of inflamed skin, with groups of pustules, and rather a superficial encrustation forming upon it, at all events is contagious. I suppose we cannot very safely trust in practice to the non-contagious nature of the other forms, so that I should be inclined, practically speaking, to act on the idea that all states of this pustular disease of the hairy scalp are capable of communicating the affection from one individual to another.

It has been represented by some of those who have great experience in these com-

plaints, that one form of the disease will produce in another individual a different form—that is, supposing one to have porrigio scutulata, it will produce one form of the disease in one person, in a second another, and in a third another; so that the form produced does not so much depend upon the exact nature of the matter communicated as on some circumstance existing in the constitution of the individual in whom the disease occurs. This is a point, however, not yet very accurately ascertained.

Now inasmuch as this disease, in a great proportion of cases, arises from contagion, so of course you do not always see any circumstances in the health of the individual capable of giving rise to it; you find, in fact, in many instances, that this affection arises and exists for a great length of time in children who are perfectly healthy, who have a good appetite, in whom there is a regular performance of the digestive functions, and in whom all other parts of the economy seem in a natural and healthy state.

It has been a question whether porrigio must actually proceed from contagion, or whether it may be developed originally under any particular combination of circumstances independent of contagion. On this point I have not, for my own part, any facts capable of elucidating the question; but I find that some of those who have seen the affection very extensively, are of opinion that porrigio may arise in an individual under particular circumstances, either of the state of health of the individual, or of the circumstances in which he is placed, independently of the actual communication of infectious matter.

The treatment of this disease cannot be conducted on one and the same plan under all circumstances. You have, in the first instance, an active inflammatory complaint; the period of inflammation passes by, and you have then a long chronic stage of the disease. You would not find one and the same treatment advantageous in the period of active inflammation and in the chronic stage. In the inflammatory stage you must employ an antiphlogistic treatment: you may find it necessary to put on leeches—to apply them behind the ears, or on some part of the inflamed scalp. You may apply cold applications, as saturnine lotion, or spirituous lotions, to diminish the temperature of the inflamed skin;—you may apply soothing applications, tepid ablutions, or warm fluids of an emollient kind, such as warm water poured on bran, or milk and water, and mild unctuous applications. These, combined occasionally with bread and water poultices, are the applications to the state of inflammation. With these means you would unite such mild internal remedies as are calculated to lessen the inflammation. It is a matter of great consequence to keep the surface of the affected part clean and free from

the discharge which is produced: there is some difficulty in accomplishing this, in consequence of the discharge being retained by the hair—the hairs become matted together, scab, and encrust. Now it has generally been said that you should have the hairy scalp regularly shaved and cleansed; but you cannot have the scalp of a child, when active inflammation exists in it, shaved: the irritation of the operation would rather aggravate the complaint: in that state of inflammation, therefore, you must be contented with cutting the hair short with a pair of scissors: you thus bring it to a state in which you can easily cleanse the part, so that you do not want the actual process of shaving. When you come, however, to the *chronic* stage of the affection—when the skin is no longer in that condition of tenderness which is produced by active inflammation—the regular operation of shaving may be performed. But even here the question would seem to be, whether in that state of the skin it is wise to adopt the process, or whether the slight wounds and irritation inseparable from the process may not actually produce greater mischief than the removal of the hair will accomplish benefit. Under such circumstances, you must be contented to cut the hair short with scissors. Now very rough methods have been recommended with a view to getting rid of the hair from the diseased surface: thus it has been recommended to apply rags spread thickly with ointment, principally composed of pitch, and when these have become fixed, you are to tear them off with the hair attached to them, and to repeat this process till you have got the scalp clear. This is a rough and unscientific mode of proceeding, and I cannot at all recommend it. Again, it has been recommended to take forceps and draw the hair out by the roots; but this is equally objectionable, and indeed is hardly a practicable proceeding. Lately, in France, they have adopted a plan for applying what are called *depilatory* substances to the affected scalp—substances which have the effect of loosening and destroying the hair: the active part of these chiefly consists of quick lime.

The mode in which these depilatories are used is, in the first instance, to apply linseed or other poultices to the surface of the head, and to wash the part very carefully with soft soap and water every day; and thereby, in the first place, to get rid of all scabs and encrustations, and then to apply over the surface thus denuded (having cut off the hair as close as you conveniently can with scissors) this depilatory substance. There is a formula of this kind given in the work of Rayer, in which he directs that one ounce of lime should be combined with two drachms of the subcarbonate of potash and one drachm of charcoal, and mixed with as much lard as will make an ointment, which is to be spread

thickly over the infected parts. A certain quantity of hair will come off; and this application is to be repeated until the surface is completely denuded. Another formula of such depilatory applications consists of twelve drachms of quick lime, ten drachms of starch, and one drachm of sulphuret of arsenic, (a bright yellow substance), and this is to be employed in the same way. I have not seen these depilatory applications used, but I should conceive, if they be capable of removing the hair, that this is a much more eligible mode of accomplishing that process than by the application of pitch, or the method of tearing out the hair by the roots by means of the forceps. But of course it is only to be employed in those instances in which the state of the scalp prevents you from removing the hair by the shorter mode of shaving.

When the complaint is in the *chronic* stage, then we can safely employ those active and stimulating substances of which I have already had occasion to speak to you. The sulphur, tar, and mercurial ointments, are perhaps the best for these cases, and they are commonly used in combination, any two being united together in equal parts. They should be spread pretty thick, and applied tolerably copiously, the diseased surface itself having been previously well cleansed by means of soft soap and water. Then the head should be covered with a light linen cap. The plan which is generally employed in these cases, that of placing an oil skin cap on the scalp, is objectionable. It confines the perspiration, irritates the part, and heats the head. The tar ointment is not unfrequently used, and with considerable advantage, in these cases; and sometimes it is rendered more active by the addition of the sulphate of copper; two drachms of sulphate to one ounce of the tar ointment. Then various astringent substances are applied, in the shape of lotions, in these affections. I may mention that the lotion of acetic acid, which I spoke of in my last lecture, is occasionally used, the parts being lightly sponged over with it before the tar and sulphate of copper ointment, for instance, are applied; and if we suppose that the ointment has been put on tolerably thick, it may be left on for two or three days, and it is only necessary to use the acetic lotion at such times as you apply fresh ointment. The nitrate of silver, in solution, is a useful remedy in these cases, in the strength of from two to ten grains to one ounce of distilled water. That is to be applied in the same manner as the acetic lotion, the parts being previously cleansed, and then sponged with the solution, after which the ointment is to be applied.

The complaint that I am now speaking of has prevailed extensively in a neighbouring institution to this—Christ's Hospital. A great number of the inmates of that establishment have suffered from it

in different forms, and a vast deal of trouble it has been to the medical attendants, who have very frequently applied a lotion of an astringent kind with considerable benefit. The lotion is not very unlike ink. It consists of four ounces of decoction of galls, half an ounce of distilled vinegar, two drachms of sulphate of iron, and one drachm of acetate of copper or verdigris, used as a lotion to the parts of the skin that are affected with this disease.

Such are the means that may be employed in the chronic stages of *tinea capitis*, or *porrigo*. The complaint is a very obstinate and troublesome one, and a great deal will depend on the careful application of the local means that are used in its treatment. In a great majority of instances you can do no good whatever by the employment of general means. You find the disease existing in children that are quite healthy, where you can gain no ground by attention to diet or internal medicines, the children being already healthy; therefore much depends upon the careful administration and application of local measures. You must take care that the surface be thoroughly cleansed, that the hair is not suffered to grow, so as to assist in the retention of the morbid secretion, and to add to its accumulation into crusts; and you must ascertain that the substances you direct to be employed in the form of lotion or ointment are carefully and diligently applied; and if you follow up this regularly, you will then succeed in getting the complaint at least into a tolerably quiet state; but the complete and radical removal of the disease is often a matter of great difficulty, with all the means you adopt, and all the pains you can bestow upon the subject.

Drs. Willan and Bateman mention another form of the disease—*porrigo furfurans*, which means a branny or scaly *porrigo*. Now a simply scaly state of the hairy scalp is an affection totally different to inflammation with pustules; and therefore if *porrigo furfurans* be *aborigine*, a state of the skin abounding with a branny desquamation, it must be a different disease from the pustular affection. We may observe, however, as the pustular affection advances towards a cure, a condition of the scalp commences in which there is some hardness of the parts, and in which there is a state of exfoliation of the cuticle, lasting for a long time. The part appears tolerably healthy, but if you rub it with the finger you raise a number of branny scales upon its surface. I believe, however, that besides that form of the complaint which originally is pustular, there is a kind of chronic inflammation affecting the scalp, with branny desquamation of the cuticle, without the formation of pustules. I do not know that you can do more in this case than employ the local stimuli that I have just mentioned, having the part previously cleansed by shaving and ablution.

But with respect to the state of desquamation which is consequent upon the *porrigo furfurans*, the affection may be kept up by the long continuance of different applications. If you suspect that, you had better confine yourself simply to ablution and a soft ointment, to keep the parts soft and pliant.

Then these authors mention another affection of the scalp, which is very singular; I think it is not allied to the preceding, although they have given it the same name—*porrigo decalvans*. It consists in a falling off of the hair from patches of the scalp. There is no inflammation, no formation of pustules, but a gradual loss of hair; and ultimately that part of the scalp which is thus affected becomes of a bright shining white, the bulbs of the hair themselves disappearing, and the scalp appearing like the top of the head of an old bald person. Perhaps in the early stage of this affection, by shaving and keeping the part clean we may stop the complaint, but it is rather doubtful whether we have much power of influencing this affection at all.

There is another affection, mentioned under the name of *porrigo*, which begins on the face, and principally affects that part, and which is characterized by an appearance similar to the pustular *porrigo* on the scalp. This is called *porrigo larvalis*, or *crusta lactea*. Now the name of *crusta lactea* designates two leading circumstances in the nature of the complaint. First, the formation of crusts upon the affected part; next, its occurrence during the period of suckling, hence called milk crust. This is an inflammation of the skin commencing upon the chin and about the face, leading speedily to the development of numerous small pustules, called *achores*, the discharge of which forms a thin yellowish scab, but the discharge is not so thick in its nature in this case as in the *achores* of *porrigo*; it is more fluid, and hence the French writers have called this *teigne muqueuse*. The discharge commences under the encrustations thus formed, and exudes from the margins, the encrustations themselves becoming thicker and larger. The affection extends from the original situation on the cheeks and face to the forehead, to the neck, and very often it gets over the whole of the body. It occurs not uncommonly in children of gross habit, who are over-fed, and in whom an unhealthy state of the digestive organs is obvious; sometimes it is produced as the direct effect of local irritation. Thus it will occur in consequence of *strumous ophthalmia*, where there is a copious secretion of acrid and stimulating tears, which produces irritation and inflammation of the palpebræ. It causes heat, irritation, and itching of those parts, which leads the children to rub and scratch them. This inflammation extends from the palpebræ to the cheeks and the face. The pustules that I have mentioned form on the integuments,

which become inflamed; and thus crusta lactea, or porrigo larvalis, follows as a consequence of strumous inflammation of the conjunctiva. Now in instances where the cause that originally produced this complaint continues to operate, and where treatment has been neglected, you find that nearly the whole surface of the face becomes covered with a yellow crust or scab; and hence the name larvalis:—larva means a mask, and the term is given from the circumstance of the face being covered over with a layer of scab, that may be compared to a mask.

When you see the complaint in a full state of development it has a very formidable appearance, but it is not a dangerous complaint in reality, and it is tolerably easily removed. I should mention that this is not contagious; it is not, like *tinea capitis*, capable of being communicated from one individual to another; it has no contagious property.

In the inflammatory stage you must, in the first place, if the alimentary canal is loaded, clear it out by active aperients, and then administer such mild opening medicines as will keep the stomach and bowels in a proper state; and you must regulate the diet of the individual. You must employ at this period soothing local applications, and perhaps, if there is considerable heat and redness, you may find saturnine or spirituous lotions useful, or at all events you may bathe the part with emollient fluids, milk and water, or other things of that kind; or you apply mild unctuous applications, as spermaceti cerate, elder flower ointment, &c. When the inflammation is put a stop to, then you can speedily cure the complaint by applications of an astringent kind: I think there is one application of this sort which is equivalent to all the rest—that is, oxyde of zinc, *flores zinci*. This is used, in the form of a lotion, in the proportion of one drachm to one ounce of rose water, and will answer the purpose extremely well. The zinc is not dissolved in the water, and therefore it requires to be shaken up before it is applied. You dab then the part over with it, and you thus find that the pustules are speedily dried up, and the complaint removed. This substance is sometimes used in the form of an ointment, but it is not so advantageous as the lotion. The citrine ointment, *unguentum hydrargyri nitratis*, in a diluted form, that is, one part of such ointment to four, five, or six parts of spermaceti ointment or lard, may be applied for the same purpose.

Some have entertained great apprehensions that ill consequences may arise from speedily removing or drying up an eruption of this nature. They have stated that hydrocephalus, or some other internal disease, may be produced by it. The same kind of apprehensions have existed respecting the speedy cure or removal of other forms of cutaneous

disease. Now these apprehensions are not altogether without some grounds. I should say that it would be a very imprudent course of proceeding, suddenly to stop, even if we had the power to do it, the crusta lactea when it is in the active inflammatory stage, without adopting measures to prevent the supervention of other disease. I should say that in the state of the constitution in which an active inflammatory complaint like this has arisen, if you were suddenly to put an end to it, there would be considerable risk of having the disease in some other form occurring elsewhere, as happens in many other cutaneous complaints. But when disease of the skin is treated on the principles that I have already had occasion to point out to you; that is, when you endeavour in the first instance to remove that condition of the system at large which produces the complaint—when you employ antiphlogistic means in the inflammatory period, and remove the excitement on which the production of the complaint has depended—you may then safely take any means that are necessary for removing the local disease. When you have got the system into a healthy state by these previous measures, you need not entertain any apprehension of disease being produced when the local disease is at an end. There are, however, certain forms of cutaneous affection, particularly certain scaly diseases—lepra, for instance—where it exists for a certain length of time without being entirely removed, being more active at one period of the year than another—where, probably, the individuals in whom such local disease exists derive advantage to their general health from such an affection; and therefore I think in many such cases, even if we had the power of removing the local complaint, it would not be at all wise to use it when the disease remains in a state not very troublesome to the patient. Recovery from that state might lead to more serious internal mischief. I think the notion on which these apprehensions are grounded, although not right when carried to an extreme length, is founded in truth and observation, and ought not to be lost sight of.

Elephantiasis.

I have next to speak to you of *tubercular diseases* of the skin; not viewing these exactly in the light of inflammatory affections, but rather as changes of structure, with chronic thickening and development of tubercles.

All affections in which there is organic change of a part are more serious than those which consist simply of inflammation. In inflammation there is a serious disturbance, but it is of a temporary kind. We know that the disturbance will go through a certain stage, a certain number of changes, and come to an end; but when you have actual alteration of structure, you find that you

have but little power of controlling it. Such is the case with those affections of the skin which constitute the order of tubercles of cutaneous nosologists, and of which I shall have occasion to describe to you several different forms.

The first of these is *elephantiasis*, a disease which does not belong to this climate, but which we have occasion to see in individuals who have been in those climates where the disease is not unfrequent, and who have actually brought it into this country from such situations; for it is a chronic complaint, and will last a great number of years. Elephantiasis occurs in hot countries, and the patients in whom we see it are those who have brought the disposition to it from the East or the West Indies.

In the first instance, it is an inflammatory complaint; there is a considerable febrile excitement of the system; there is an inflamed state of some part of the skin, though this is not marked by the ordinary characters of inflammation in a high degree. On the portion of the skin thus inflamed, tubercular enlargements arise, varying in size from that of a large pin's head to that of a horse-bean. Soon after these are produced, they lose the light red which they had at the commencement, and they are not deeper in colour than the natural skin. They form hard smooth knots, shining somewhat on the surface. After existing for a certain length of time they ulcerate—they form an unhealthy kind of ulcer, from which a scanty discharge takes place; it forms in thin encrustments upon the surface of the sore, and a kind of indolent ulceration is produced, which remains for a long time nearly in the same state, and then slowly cicatrizes. Fresh tubercles arise, which go through the same process—tubercular elevation, induration, ulceration, and cicatrization. Thus you will see, in a part of the body that is affected with elephantiasis, some of the tubercles in their original state as mere small, pale, shining elevations of the skin; others in the condition of ulceration, intermixed with cicatrices. This affection first shows itself in the face; it affects the forehead, eyebrows, eyelids, the nose—particularly the alæ, the lips, the cheeks, the ears; and then it attacks, first the upper, and then the lower, extremities of the body, shewing itself upon the fingers, the skin of which becomes beset with these tubercles, so that the form of the hand is much altered, being thickened and enlarged. The tubercles spread from the back of the hand to the wrist, and at length to the fore arm. On the lower extremities, the tubercles first appear on the toes, and next occupy the feet; they do not spread much up the legs, nor do they reach, perhaps, the upper arm. Great deformity is produced by the complaint in the face; the alæ nasi are enlarged, fissured, and quite altered in form. The lips become thick and very broad and

irregular in shape, and in fact, such alterations take place in the whole of the features that you would not recognize the individual. The affection is not confined to these parts; it extends to the mucous membrane lining the mouth, and the tongue becomes tubercular and ulcerated. There are tubercles on the roof of the mouth and soft palate. The entrance of the fauces is beset with them, and in this way the disease sometimes extends along the air-passages to the mucous membrane lining the lungs. In one or two cases that I have seen, the disease has ended fatally by the affection extending along the mucous membrane to the lungs. In other instances, these affections are attended with considerable depression of the general powers, constituting that kind of state which nosologists have called *cachexia*—depraved habit of body. The pulse is small and feeble; the functions, generally, are imperfectly executed; the individual is labouring, in fact, under a state of decay of constitution, and the existence of the disease, the recurrence of attacks of inflammation, and the development of new sets of tubercles, continue to depress the powers, and thus the patient sinks under the complaint: such sinking, however, does not take place till after the complaint has lasted for a great length of time.

In the inflammatory stage of this affection, you must, of course, employ such means as are necessary to check the inflammation; but in the chronic stage, so far as I have seen the complaint in this country, I think there is but little to be done by medicine. It has been supposed that arsenic, mercury, and some other active means, may be capable of arresting the progress of the complaint; but, according to my experience, all these powerful means do more harm than good; and the only plan that I have seen attended with any beneficial effect in the chronic stage, is that of giving the patient good diet, good nourishment, keeping him quiet, and not giving him any more medicine than is just necessary regularly to open the bowels. Under such a course of treatment, I have seen persons, for a time, get tolerably well, the tubercles indeed remaining, but the ulcerations healing up, and the patient attaining what we might call a good state of health for one whose constitution is thus affected; but, I believe, in the end they generally die of the disease.

Lupus.

The next affection of a tubercular kind that I have to mention is that called *lupus*, a disease occurring in the face. This is also known by the name *noli me tangere*, which, I need hardly inform you, means *touch me not*—a kind of indication of the intractable nature of the affection.

It commences with inflammation and

swelling about the nose, or some part of the face, and elevation, with a bright red and pretty active inflammation of the skin, which then proceeds to a state of foul ulceration. Sometimes, however, we do not observe any previous tubercular affection of the skin.—We see that the integuments of the nose, for example, assume a bright, and occasionally a deep livid tint from the inflammation, and then go into a condition of unhealthy ulceration, without any tubercular character. The instances in which there is a previous formation of bright, red, shining tubercles, seem to be chiefly in scrofulous subjects, in whom the complaint altogether may be deemed rather bordering on scrofula affecting the skin. In this form it occurs in young subjects. But the form of lupus which appears to be most intractable is that which occurs in adult persons, where inflammation of the skin takes place, and foul ulceration ensues; and the process destroys the parts in which it is seated, spreading with a vivid red inflamed border. In this way we not unfrequently find that a considerable part of the alæ of the nose, or other part of the organ, becomes destroyed; and, in fact, the extension of the complaint in many cases completely destroys all the cartilaginous and bony parts of the nose. The ulceration sometimes extends so as to divide the septum of the nose, so that this part very frequently is lost, or considerable destruction of it takes place, before the alæ suffer much. In the case of the tubercular disease, it not unfrequently happens that there is an affection of the cheeks, near the nose, as well as of the nose itself: in either case the affection may extend to the upper lip. The constant flow of the discharge produced by the disease over the upper lip, seems to give rise to this propagation of the disease in that direction. I should mention to you that this disease is sometimes spoken of under the name *herpes exedens nasi*. Now the term herpes is usually applied to a vesicular disease produced by inflammation, running a certain course, and then coming to an end: it is an affection, therefore, totally different from this corroding ulcer—this lupus, occurring about the nose. Of course you will conclude that this disease commonly takes place in individuals in whom there is some very unhealthy state, either of the system or of the constitution generally. I have mentioned that in young subjects it takes place in those of a scrofulous disposition, and that the form of lupus that takes place in adults is generally traceable to something in the habits of the individual—to intemperance of diet, or to some of those habits that produce plethora. You do not find it taking place in healthy persons, who live temperately and properly.

Your first object in the treatment of this case must be to remove those causes that

give rise to the affection. You sometimes find a condition of the system that renders it necessary to take blood from the arm, to employ active purgatives, to regulate the diet of the patient, and prevent the introduction into the stomach of stimulating articles, whether fluid or solid. In this period of the complaint, while you rectify the cause or remove it, you must adopt mild and soothing local measures—the application of soft poultices, tepid ablutions, and mild unctuous applications. These are the means that should be applied locally; but when you have accomplished all you can by these means, then you must apply other and more active local measures, to put a stop to the foul and unhealthy kind of ulceration, from which the discharge keeps constantly exuding. The nitrate of silver in solution is a very useful application of this kind. It may be applied by means of lint under a bread and water poultice. Then long experience has established the efficacy of arsenical applications in these cases; and these means have produced so much good in cases of these corroding ulcers about the face, that hence has arisen the reputation which arsenic has acquired as a remedy in cases of cancer generally, because the ulcerations on the face have been deemed cancerous, though there is really nothing cancerous in their nature. The liquor arsenicalis, of the London Pharmacopœia, is a common form of using this remedy locally. In some circumstances you must dilute this with distilled water; under others you must apply the liquor arsenicalis of its full strength, which will frequently produce a superficial slough of the part to which it is so applied. The arsenical remedy has been used of various degrees of strength, by different practitioners. Dupuytren uses it generally in cases of this kind, but in a very mild form; he employs a combination of arsenic and calomel; 199 parts of calomel, and 1 part of white arsenic, sprinkling the powder copiously upon the part, and repeating the application frequently. There is a French remedy, consisting of ten grains of white arsenic, two scruples of cinnabar, and one pinch between the finger and thumb of the ashes of old shoes—I suppose any other inert substance may be as well employed as the latter ingredient: now this is to be made into a paste with saliva, and the paste thus formed is to be spread upon the surface of the sore. It is a tolerably active remedy, and capable of producing a slough; and when arsenic is employed in that way it completely destroys, to a certain depth, the parts to which it is applied, and converts them into a tough, dry, yellow, or brownish inorganic substance, which separates and sometimes leaves a healthy surface. Rayer and Dubois use another for-

mula—that is, half a drachm of arsenic, one ounce of French vermillion, and half an ounce of dragon's blood. This also is to be employed in the form of a paste, being mixed either with saliva or mucilage. The strong form of arsenic produces decomposition of the surface to which it is applied, giving rise to a slough; while in the milder form it is little more than an active stimulus to the parts. The white arsenic may be used in the form of ointment, mixed with spermaceti cerate: one scruple of white arsenic to half an ounce of spermaceti ointment will make an active application, capable of producing a slough. There can be no doubt that this is a powerful remedy; but you will recollect that arsenic, when applied either to a recent wound or to an ulcer, is capable of producing the same poisonous effects on the animal economy which it will produce when introduced into the stomach; therefore you must not employ active forms of the remedy to any considerable extent of surface. If you have a large surface you must employ a mild form of the remedy, or else employ the more active form only partially. You must be very much on your guard in using this remedy. By these and similar applications, ulcers having the character of lupus are very often put a stop to; but it commonly happens that they produce considerable destruction of the part in which they are situated before this object is completely accomplished. Sometimes the ulceration destroys one side of the nose, frequently the septum, and not uncommonly the entire organ. But though intractable, the complaint is not necessarily malignant; indeed, its worst effects consist in the deformity it produces, by the destructive progress of the ulceration.

CASE OF THE HYDRENCEPHALOID AFFECTIO OF INFANTS.

COMMUNICATED BY

MARSHALL HALL, M.D. F.R.S.L. &c.

THE following case, for which I am indebted to H. E. Church, Esq. is peculiar, and highly deserving of being recorded, on account of the affection having *originated* in other causes, and been *continued* from exhaustion. This event is not unfrequent in its occurrence; yet no example of it is published either in my own Essay or the subsequent one of Dr. Good.

“DEAR SIR,

“That form of debility and hydrecephaloid affection to which, in your

late work, you have directed the attention of the profession, has been well exhibited, I think, in the case of my own child; the following account of which may not prove to you uninteresting.

“H. E. C. aged two years and seven months, was born healthy, and continued so for five months, when, without any evident cause, great cerebral disturbance and violent convulsions ensued, which symptoms were restrained by active bleeding, the free exhibition of calomel, and the frequent use of the warm bath.

“On a recurrence of the symptoms, which repeatedly happened during a period of nine months, a similar practice was pursued, with the addition of freely lancing the gums.

“Some time afterwards a very severe attack of inflammation of the brain, accompanied with the same alarming symptoms, was again effectually subdued by the same mode of treatment.

“The little sufferer, after a short interval, again became subject to muscular twitchings, dilated pupils, and throbbing of the fontanels, which had continued remarkably open. The brain or its membranes were supposed once more to be inflamed. In this last accession, however, the skin was free from heat, the tongue moist and clean, and the pulse small and thready. Under these circumstances, ammonia was instantly administered, and afterwards, from time to time, wine, in combination with sulphate of quinine. The alarming symptoms quickly subsided, and a gradual and perfect recovery was effected.

“Should you deem the foregoing remarks worthy of your notice, you may make what use of them you think proper. I regret that a more circumstantial detail of symptoms cannot be given, as I failed to make any notes of the case at the time.—I remain,

“Your obedient servant,

“H. E. CHURCH,

“Memb. of the Coll. of Surgeons.

“To Dr. Marshall Hall.”

This is not the only example of morbid affections arising from one cause being protracted by another and very different one. Pain, and other affections of the head, the effect of intestinal irritation, is frequently, first relieved, but then aggravated, by giving purgatives, or otherwise inducing irrita-

tion of a different kind, or exhaustion. The interesting observations of Mr. Brodie (*Medico-Chirurgical Transactions*, Vol. xiv. p. 381) exemplify this remark. The subject is treated of at length in my *Researches on Blood-letting*.

April 22, 1830.

SPASMODIC AFFECTION OF THE UTERUS.

To the Editor of the London Medical Gazette.

Eton, April 1830.

WRITERS on midwifery tell us, Mr. Editor (and among the rest my excellent preceptor, Dr. D. D. Davis) of a spasmodic affection of the uterus which they denominate "the hour-glass contraction," an affection which I imagined I had several times met with, and overcome by a large dose of laudanum and manual efforts, gradually relaxing the spasm. It happened, however, at a late meeting of the "Windsor and Eton Medical Society" that Sir John Chapman, of Windsor, a gentleman of great experience, and very extensive practice, when speaking on this subject, gave it as his decided opinion that no such affection as hour-glass contraction of the uterus existed—an opinion which, I confess, staggered me at the time, as strongly militating against my own experience as well as all our best authorities on the subject. The following case, however, which lately occurred to me, has so strongly convinced me of the truth of that opinion, that I am desirous of detailing it, for the judgment of the profession.

Case of Retention of the Placenta from long continued Spasmodic action of the Uterus, induced by sudden traction of the Funis.

A woman, 35 years of age, of healthy appearance, and at the full period of gestation of her first child, was seized with uterine pains on Wednesday morning, 7th April, which continued during the day at irregular intervals. In the evening, there being no dilatation of the os uteri, and that organ being high up in

the abdomen, an opiate was given, which produced a quiet night, and the following morning an aperient, which did not act till late in the day. Thursday was passed as the previous day, with small irregular pains, and no advancement of the labour. On that night, however, or rather at two o'clock on Friday morning, the patient, on getting out of bed to the night-table, was seized with two pains, which expelled the child with such force that the funis was separated from the placenta, close to its origin. I was sent for on the instant, and found the patient without either pain or hæmorrhage; the uterus firmly contracted, and feeling like an immense stone in the abdomen. After remaining a couple of hours, and finding no expulsive efforts made by the uterus, I passed my hand into it, as I imagined, (my arm being introduced up the vagina to within three inches of the elbow), for the purpose of removing its contents, when I found a firm constriction in its centre, and a portion of the placenta hanging loosely below it. I gave all the laudanum I had by me at once (about 5j.) and endeavoured for some time to dilate the spasm, but failed. I then left the patient, with directions to be sent for in case of hæmorrhage, and prescribed an anodyne medicine, to be repeated at intervals. She remained without hæmorrhage or an expulsive pain during the day, the uterus firmly contracted in the abdomen. At six o'clock P.M. I renewed my efforts to extract the placenta, but found the uterus in precisely the same state, and was compelled to desist. At eleven at night I gave the patient thirty drops of Battley's liq. opii. sedativ.; and at 12 o'clock I again introduced my hand, and found the spasm as rigid as before. I then pressed my left hand on the abdomen, and found, to my surprise, from the shape and situation of the uterus, that my fingers had never been within it at all, but that its mouth was firmly closed on the placenta, and that the uterus had receded so high into the abdomen, thereby elongating the vagina to so great an extent as led me to suppose I had found my way into the middle of the organ, when, in truth, I had but arrived at the portal. I now directed the nurse to press very firmly on the fundus uteri, in opposition to my efforts to dilate its mouth, and by half after twelve o'clock I succeeded, by very strong exertions, in re-

laxing the spasm so as to admit my hand, and immediately withdrew the placenta, the uterus instantly returning to its former state of rigidity. Three parts of the placenta had been retained within the uterus; there was no appearance of adhesion to its surface, no hæmorrhage succeeded, and the patient did well.

With best wishes for the success of your valuable publication, believe me,
Mr. Editor,

Very truly yours,
WILLIAM MOSS.

COLLEGE OF PHYSICIANS.

To the Editor of the London Medical Gazette.

SIR,

I TAKE advantage of your widely-diffused and justly-patronized Gazette to call the attention of those who are labouring under the same privation as myself, to consider the best means of obtaining redress.

I am a Licentiate of the College of Physicians of London, and among the numerous fees exacted on admission, I find one of 32*l.* "to the College." I should be glad to be informed if this sum, or any part of it, goes towards the support of the library; and if so, why I am not allowed the perusal of the books contained in it? This I consider the greatest privilege that could be granted, and a privilege that every Licentiate is bound to contend for. I have visited most of the principal cities in Europe, but I blush when I declare that in none have I found such impediments thrown in the way of medical instruction as in this.

If any one through the medium of your Gazette will suggest the means best adapted to obtain this privilege, I am convinced he will meet with support from every enlightened member of the medical profession.—I am, sir,

Your very obedient servant,

A SUBSCRIBER.

8th April, 1830.

[We believe there is no library fund, and, in fact, that the College possesses very few modern works; so that the privilege would not be so valuable as

our correspondent seems to suppose. We know of no mode of obtaining it as a right; but as an act of courtesy any Licentiate may easily procure admission through the medium of the censors or curators of the museum. We would, however, suggest to the College, that it might be advantageous to all parties if they would institute a fund for the support and increase of the library. Suppose Fellows and Licentiates were to pay from three to five guineas per annum, all having equal right to the use of the books. This might be done on the same principle as at the Royal Institution, where the subscribers have the privilege of attending the lectures and visiting the library—without, however, their being considered members of the Institution.]

ANALYSES & NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abrégé."—D'ALEMBERT.

Observations on the Structure and Diseases of the Testis. By SIR ASTLEY COOPER, Bart. F.R.S. Serjeant-Surgeon to the King; Consulting Surgeon to Guy's Hospital, &c.

OF those young authors who write on practical subjects before they have acquired experience, one speaks according to circumstances. It sometimes appears that they are meritorious, industrious young men, who resolve, in a manly and open manner, fairly to enter the lists and compete with all comers, but without affectation or undue pretension; and such aspirants after fame we are naturally disposed to treat with courtesy. Sometimes, again, we see one just from the schools putting on the grave character of wisdom and experience, and speaking of what he has seen and what he has done; and towards such it is impossible to feel indulgent. On the whole, how differently are the best of such competitors for notice to be estimated from those who, in the maturity of life, and with a grateful sense of public favour, sit down to give the profession the benefit of their experience. Sir Astley Cooper has no character to win, but, on the contrary, much to risk. He cannot be sus-

pected of mercenary motives, for every one must acknowledge that he may, if he choose, be more lucratively employed than in writing books. We, therefore, commence our review of his new work with the conviction that we owe it to a pure source—a sense of duty, and the hope of alleviating human suffering. It is, indeed, but the continuance of that active life in aid of his younger brethren, formerly displayed as a teacher, and now exhibited to us in the mode best becoming our author's matured experience and rank in his profession.

What first catches the eye in this publication is the plates; and we frankly confess, that in them we are disappointed. The great work of this author on *Hernia*, is creditable to the age and to the country; the dissections were accurately made, the drawings and engravings beautiful, and they will remain a testimony of his liberality, when these coloured lithographic drawings shall be forgotten. Lithography is a curious and a beautiful art; but we would recommend to Sir Astley Cooper, in his future works (for we are covetous of more), to take the advantage which fortune has given him, and to employ the burine, rather than the stripling pencil of lithography.

The present volume is a large quarto of 245 pages, divided into two parts, illustrated with 24 coloured plates. The first part contains the *Natural Anatomy of the Testis*, and the second part, its *Pathology and Morbid Anatomy*. We shall first notice the author's anatomical demonstration of the testis, which we find to be the same that he was accustomed to give in his lectures;—and here we take the opportunity of recommending to young lecturers the minuteness and accuracy displayed in the anatomical details of this veteran in teaching. It may be well for those who have fallen into a slovenly and superficial method of demonstrating—omitting the details, and attending to what they call “surgical anatomy” alone—to observe that the men who have been so distinguished as practical surgeons, acquired the confidence of their pupils, and ultimately of the public, by such labours as these. It may justly be said that the schools of anatomy and surgery in London acquired their present high character by the same strict and explicit way of demonstrating all

parts of anatomy which we have exhibited to us here; and that this character can only be maintained by constant attention to the foundation on which it was raised.

We find in this division of the work, an account of a new method of injecting the seminiferous tubes of the testicle, adopted by our author; and the success attending it has been highly satisfactory. It is known to every anatomist how difficult it is to obtain an injection of these tubes by the common method of pouring mercury into the *vas deferens*. The history of this department of anatomy acquaints us with the unsuccessful attempts of Haller, who could not get the fluid to pass further than the *rete testis*, and of the elder Monro, who was even less successful; and how it was reserved for the Hunters first to shew these *tubuli seminiferi* injected with mercury. And here we cannot but recal the violent disputes between Dr. Wm. Hunter and the second Monro, founded on this very point, which proved, at all events, the zeal with which these eminent men cultivated minute anatomy. We have ourselves experienced frequent disappointments when attempting to inject these vessels, and yet we have been successful; but it has been, we must confess, through good fortune, rather than any good management. The preparations of successful injections of the *tubuli seminiferi* in this country, might, we undertake to say, be very easily enumerated. But even after obtaining a good injection with quicksilver, the dissection and examination of the structure of the gland can only be prosecuted at the hazard of wounding the vessels, and letting the quicksilver escape. Hence these preparations, however splendid they may be, (when the whole body of the gland appears one mass of silver, immersed in clear turpentine, and spread out upon red paper,) are almost useless for the minute examination of the testicle. Sir Astley Cooper fills these tubes with a coloured solution of glue; and it is obvious how this does away with the objections which we have mentioned. He throws this coloured glue into the tubes which form the *rete testis*, using a fine pipe of silver, or of steel; and not only are the *tubuli seminiferi* injected, but the *vasa efferentia* are also filled. The drawings of the preparations made

by him in this manner, sufficiently shew the advantages resulting from it in enabling us to unravel the minute texture of the gland.

We regret that, in the account of the coats of the testicle, Sir Astley has countenanced a method of describing the tunica vaginalis which must render the study of our best writers difficult. We may ask, why should the nomenclature of our author be different from that of Haller, Hunter, Pott, Warner, Sharpe, Earle, Ramsden, &c.? These are authors whose works the diligent student must read, and of course he must understand their terms. They all agree in calling the outer loose covering of the testicle, *tunica vaginalis*; and the internal, smooth, white covering, which adheres to the body of the testicle, *tunica albuginea*. It was between the tunica vaginalis and the tunica albuginea that they said the cavity was formed into which the fluid of hydrocele was secreted—into which the intestine fell in congenital hernia, &c. Sir Astley Cooper, on the other hand, terms the first coat (*i. e.* the tunica vaginalis) *tunica vaginalis reflexa*; and the second coat (*i. e.* the tunica albuginea), *tunica vaginalis testis*; while he applies the term *tunica albuginea* to what may be considered a newly described coat—one which lies under the last, and embraces closely the glandular texture of the testis.

Let us consider the origin of the old names. The terms of human anatomy, it is known, are frequently to be traced to resemblances found only in brutes. Thus in dissecting the testis of a dog, or a calf, or a sheep, the anatomist lays open a regular sheath, or vagina; not a mere sac enclosing the body of the testicle, as in the human subject, but a scabbard, sheath, or vagina, extending from the lowest point of the epididymis to the abdominal ring, where its opening is. Nothing can be more appropriate than the term vagina, applied to this loose outer coat; accordingly it has been received by all authors; and when they saw lying within this sheath the testicle itself, invested closely by a membrane, which was of uncommon whiteness, they naturally called it tunica albuginea.

The discovery of the descent of the testicle led to new ideas about these membranes. When it was observed that the testicle lay originally in the ab-

domen, it was found that the membrane closely attached to the body of the testicle was precisely in the same circumstances with the investing peritoneal covering of any of the abdominal viscera. At all events, this membrane was clearly the first coat which the testicle had from the peritoneum; and the vaginal coat was the second, which it received only after its descent. To say, therefore, that the tunica albuginea of our best authors is a *tunica vaginalis*, is just that sort of inaccuracy which is apt to puzzle the student; since, in matter of fact, it is not a sheath or vagina, nor any thing like it.

If, in dissecting the testicle, we opened a membrane like a sheath, and called it vaginalis, and were to trace that over the face of the testicle, there would be some reason for calling this part of the membrane *tunica vaginalis reflexa*; but by this new nomenclature we apply the term vaginalis to this inner coat without any reason, and call the outer one "*reflexa*," in consequence of the peculiarity to which the term vaginalis is applicable—if applicable at all. We must acknowledge, however, the propriety of distinguishing both the peritoneal or serous coverings from that membrane intimately connected with the proper substance of the testicle, and called by our author tunica albuginea; which term, we repeat, is only objectionable as used by Sir Astley, because it is not what is meant by the same term as it is used by our best authors.

At the end of the first part, the author has related some remarkable cases, shewing the effects of removing these organs in the living body. After stating the first case, he continues:—"From this man's declaration I believe that the history of eunuchs, if perfectly castrated, has been very much misrepresented; for it would seem, that after a few months, he lost all seminal emission, but that the erectile power remained for a few months more; and then, excepting at very distant periods, and but imperfectly, even that power ceased, and the penis became shrivelled and diminished."

"The second case in which I removed the testis, was in a lad, in Gny's Hospital, aged sixteen years, who had previously the other testis extirpated. The disease each time was a scrofulous abscess, with subsequent ulceration,

The lad had not reached puberty, and he was very weakly and emaciated. Five years afterwards, as I was stepping out of my carriage, at a patient's door, a fat, sleek-looking, young person said, 'How do you do, sir?' I said, 'Very well; but I do not know you.'—'Have you forgotten removing my testicle, in Gny's Hospital, five years ago?' 'O yes, I recollect you; you look very well.'—'Yes, but I am very unhappy;' and he immediately burst into tears. 'Why, what do you lament?'—'Oh, sir, that I am not as other men. I often wish that I were dead.' Desirous to cheer him, I said, 'You are a lucky fellow, for you are saved from many evils.' He shook his head, and I left him sorrowful."

We naturally think of referring here to the parallel facts with relation to the other sex, as stated by Mr. Pott. We must remark, however, that the curious results from Mr. Pott's operation have carried the profession away from the consideration of the propriety of his practice; a practice which, we think, was altogether unwarrantable. The ovaria presented at both groins in a woman in the situation of inguinal hernia, and he extirpated them! The effect of this extirpation was, to change the female character of the individual, and to produce a resemblance to the male. The best view of this subject is, perhaps, that given by Mr. Hunter, which is essentially this, that both the male and female organs are superadded parts; that they are not necessary to the economy; and that, but for their addition, the human frame would have a form and character differing from either sex. Thus, in a child before puberty, we often mistake the sex; the lively girl having something of the boldness of the boy, or a modest boy the soft look of the girl. The development of the male organs produces an entire change on the frame; strength of character and firmness of bodily figure result: whilst under a corresponding change of organization, the bold little Miss acquires the more modest feminine graces, and becomes ashamed of that boisterous activity which belonged to her in childhood. It would appear as if there were an intermediate state; and that it required the superimposing of either one or other of these organs to develop all the marks or features by which the sexes are distinguished. The jockey

attends to this who is desirous of having a horse high in the fore quarters, partaking, that is, of some of the characters of the entire horse; for he defers the operation of gelding until the animal has had time to acquire that peculiar form of the skeleton which the presence of the testicles bestows. It is not many years ago since Mr. White, of the Westminster Hospital, drew up an account of a boy, the "Infant Hercules," in whom the external organs of generation, to appearance in full maturity, were appended to a child, producing a singular combination of the resolute and pugnacious character of a lad with the intellect of a child. Soon after this, there appeared another infant, a still more disagreeable monstrosity, having a development of the exterior parts of the woman, with the other general characters of the adult also formed. In the decline of life, when the same organs lose their natural functions, some will assert, that we have another opportunity of observing the influence which they possess over the general frame. It has been remarked, that the two sexes have then a tendency to relapse, as it were, into the common or intermediate form. This was observed by Mr. Hunter in birds; the hens of different kinds, as of the pheasant or peacock, when they grew old and ceased breeding, assumed the plumage of the cock, and even the spurs. These circumstances sometimes may apply in consultation, inasmuch as there may be a weakness of mind or a deficiency of character in an individual; and on more particular inquiry, this will be found to be attended with, and perhaps produced by, an entire want of sexual appetite.

In another number we shall proceed to the more interesting part of the volume, which treats of the pathology and morbid anatomy of the testis.

CASE OF INTUS-SUSCEPTION,

*With Sloughing of a large portion of Intestine,
voided by Stool.*

By LEVI GAYLORD, M.D. of Sudus,
New York.

In the month of October, 1827, I was called to the house of the Rev. William

Stone, of this town, to attend on his grandson, William Henry, then about six years of age. His first symptoms did not indicate a very severe attack. A cathartic was administered, which operated readily, and with apparent efficacy. On the following day he began to complain of pain in the bowels, attended with considerable fever, which continued with increasing severity for two or three days, until nausea, stercoraceous vomiting, and the usual symptoms of the most obstinate constipation, or intus-susception, were distinctly prominent.

Bleeding, blistering, cathartics, often repeated, beginning with the mildest, castor oil, Epsom salt, followed by jalap, calomel, croton oil, &c. with enemata frequently administered, (two or three occasionally of tobacco,) and Dr. Hosack's emetic process, with the warm bath, were severally and unitedly resorted to, and persevered in, under my personal direction and inspection, for about four days.

The acuteness of the pain, the intensity of the heat, together with the accelerated pulse, reddened, shrivelled, dark-furred tongue, and great prostration of strength, indicating a tendency to putrescency, left us scarce a shadow of hope that the termination of the case could be favourable.

In about four or five days, an evacuation was procured, of a dark briny appearance, somewhat of an indigo tinge, followed by a speedy mitigation, and soon by an entire alleviation of all the alarming symptoms.

This discharge was succeeded by one or two rather copious discharges, exhibiting nearly the same appearances. The evacuations soon became natural, the bowels open and regular, the febrile symptoms disappeared, the tongue cleared, the appetite returned; in short, the whole system appeared with unwonted rapidity to resume its ordinary functions, and place him in a most favourable and convalescent state.

In a little more than two days from the opening of the bowels, I believed and declared my patient out of danger, and left him without any appointment to see him again, but the next morning was summoned to attend him, as his symptoms were materially worse, and "an astonishing appearance presented itself, from the bowels having come down."

I immediately repaired to the house, and found a portion of the intestines protruding in two doublings or folds of several inches in length. Most of the intestine thrust out was in a state of incipient mortification; some more advanced in the putrifying process; and other portions exhibiting a nearly natural appearance. In this state I should not have thought that any person who had ever seen or handled an intestine, would have doubted whether this was such. I immediately gave up the patient for lost, and notified the family of what I considered the inevitable result. I, however, applied a poultice of charcoal and yeast to the part, directed a saturated decoction of cinchona, and also brandy, to be administered as the stomach would bear, and nourishing broth to support him while he lived.

In about twenty-four hours, the protruded portion of the bowels sloughed off: it measured twenty-three inches in length, exclusive of about three inches contained in a fold, which adhered too firmly to be detached or extended, and which I supposed has formed the origin and laid the foundation of the difficulty and obstinacy developed in the progress of the disease. * * *

After the separation of the detached portion of the bowels, passages were procured, though with considerable pain and difficulty. The evacuations put on much the appearance of the fermenting wash in a distillery. Digestion was very imperfect; emaciation to an extent but rarely witnessed ensued; and the assimilating powers of nutrition were so feebly maintained, that the lamp of life gleamed feebly in its socket, and was momentarily threatened with entire extinction.

In this state he continued with little alteration for several weeks, when a novel and interesting feature of the complaint was gradually developed, until it became the prominent characteristic of the case.

The pain, which had been pretty constant, gradually became periodical, until it assumed all the regularity of parturient pains, in its returns, varying from five to fifteen minutes between each successive paroxysm. The voice also was precisely of that kind which distinguishes such pains, uttering those cries which indicate the most piercing distress, and which might be heard to a considerable distance from the house.

Each paroxysm lasted about a minute and a half, and was succeeded by an interval of perfect ease. On the return of each pain, the abdomen, which before was jejune and contracted, suddenly grew distended and inflated, discovering through its thin parietes, every movement and tortuous winding of the intestinal tube, each portion of which seemed endeavouring to force its way through the thin integuments which enclosed it, and exhibited a tympanitic hardness and tenseness seldom witnessed in the most obstinate diseases of that kind, but which instantly and entirely subsided in exact ratio to the pain.

This distressing symptom was treated during some weeks with antispasmodics, anodynes, blistering, fomentations, and gentle cathartics, with every means which I supposed might enter into a palliative or curative course of treatment. At length I resolved on a mercurial course, notwithstanding the extremely low state of the patient, and to my great satisfaction this troublesome and distressing symptom subsided, as soon as I had carried it to the point of gentle and moderate salivation.

Health was gradually restored, and at this date, (about two years since the period of the attack,) my former patient is a tolerably healthy lad, subject, however, more than ordinarily, to attacks of colic and other bowel complaints*.

Sodus, N. Y. Sept. 29, 1829.

ANATOMICAL MODELS.

To the Editor of the London Medical Gazette.

SIR,

I AM induced to offer a few remarks upon the subject of anatomical models, imitative of natural or diseased structures, elicited by the notices which have recently appeared in the *Medical Gazette*†, not merely for the purpose of rectifying the misconceptions to which those notices might give rise, but also to direct the attention of the students and junior members of the profession to the cultivation of an art hitherto supposed to be so difficult and mysterious

as to have been excluded from consideration as an useful and improving auxiliary in a liberal course of surgical education. To those who are aware of the impracticability of preserving the forms, colours, and appearances of anatomical specimens of various parts of the body, either in wet or dry preparations, the value of an art which enables its possessor to imitate and to fix natural or morbid appearances, with all the vividness under which they at first presented themselves, must be sufficiently obvious; and by selecting useful subjects, either of pathological or of surgical anatomy, the means of valuable and practical reference may always be at hand; for if the imitations be accurate and faithful, every visual impression which the original could make may be preserved for any length of time. Although the intrinsic value of such productions, when completed, is very considerable, I believe it is yet much less than that which the surgical student, anxious to qualify himself for the duties of actual practice, derives from the more severe study of relative and surgical anatomy, the knowledge of which forms the very groundwork of any approach to excellence in this art as relating to the useful and practical purposes of surgery. In this art, as well as in every other art or science, there are difficulties to be surmounted, yet it may be acquired by whomsoever is willing to pay the price of accurate observation, and of persevering labour and study. If the difficulties likely to occur to every novice, and the niceties of attention absolutely required to render any such imitation faithful, be demonstratively explained, the labour may be much abridged, and many fruitless, and therefore discouraging attempts, be obviated. The hidden treasure sought will not be found in the shape of gold, but in the increased power attained by the surgical student, through the severe exercises which such productions entail upon him.

The remarks in your number of March 6th, (p. 736), under the head of "Wax Models," if allowed to pass unnoted, would lead to a very erroneous impression that Mr. Towne was the only Englishman who had the merit of introducing, or of creating wax modelling in this country in the representation of anatomical or morbid specimens. So far from calling in question Mr. Towne's attainments and success in his,

* Amer. Journ. Med. Sciences, Feb. 1830.

† Pages 666 and 736, vol. v.

art, I believe him to be deserving of high commendation; but the zeal of your correspondent, who states, on the authority of Dr. Hodgkin, that "he created his own art," (if by his own art he meant that of imitative modelling in wax, or other materials, so as to represent the various structures of the human body), requires to be received *cum grano salis*.

Whoever had observed, even so far back as twenty years, or more, the beautiful specimens of imitative modelling in wax, or other combined materials, in the museum of Mr. Charles Bell, when that museum was in London, the work of one who unites, in an eminent degree, the talents of the anatomist and surgeon with those of the artist, must be aware that in truth to nature, and in richness of effect, these specimens were not only equal to, but even superior to those of the Foreign schools. Had Mr. Bell been as willing as he was able to divulge the means by which such splendid effects were produced, I doubt not that long ere now the practical value of such exercises would have been so fully appreciated that every surgical student, ambitious of more than common-place attainments, might have so far cultivated this useful and elegant art, as to be enabled to make permanent fac-similes of his own most important dissections in surgical and pathological anatomy, the practical uses of which to the surgeon are of far higher value than the mere pleasure which such productions of art are capable of affording to the eye*.

* All the information which one of Mr. Bell's pupils, who was anxious to learn, or even to glean a hint relating to this art, which might enable him to imitate his teacher, to whom he looked up with admiration, could obtain was, "that it was done after the manner of the encaustic painting of the ancients." It is not, however, to be expected that Mr. Bell, or any other teacher of medicine or surgery, should, without an adequate consideration, give up his time and the fruit of his experience, to enter into the details of an art (although that art may be a valuable auxiliary to medical or surgical knowledge) which he may have cultivated, but does not profess to teach. Many persons who have freely promulgated their discoveries in science (and few have contributed to medical science more extensively, or with greater honour to themselves, than Mr. Bell has done), have yet been reluctant to communicate, in collateral or minor matters, that information which it had cost them great sacrifices of time and experiment to arrive at; but which, when the difficulties had been thus surmounted, might be communicated to others, perhaps in one-tenth part of the time originally sacrificed—to others whose habits and previous attainments would never have enabled them to surmount the difficulties by their own unaided powers.

For some successive years, the society for the encouragement of arts, &c. in London, had offered their highest premium—their gold medal, for the production of coloured anatomical models in wax, or other substance, without a single claimant. By a reference to the records of the society, you may ascertain that the first candidate who was rewarded for anatomical wax-modelling, was Mr. John Rutherford Alcock, a surgical student, who in 1825 received the gold Isis medal; and in 1826, the highest honorary reward which the society bestows, the large gold medal. Now the conditions attached to these rewards, required that the candidate should execute openly, in presence of the committee of polite arts, which committee was open to every member of the society, specimens in verification of those rewarded, thereby disclosing the manner in which the entire process was conducted; so that difficulties, which it had cost great sacrifices, both of time and of expense to overcome, were removed in relation to those who might choose to profit by the knowledge which he had thus freely communicated*.

The same records will shew that Mr. Towne did not present any coloured anatomical models in wax, in claim of the premium offered for that purpose, until the year after Mr. J. R. Alcock had received the large gold medal, although Mr. Towne was in 1826 rewarded with the large silver medal of the society for

* Extract from the Address delivered at the public distribution of the rewards of the Society of Arts, May 29th, 1826. Read by the Secretary, Arthur Aikin, Esq.:—

"Surgical Students.—It is now three years ago since the Society first began to offer premiums in the class of polite arts expressly for surgical pupils.

"They were induced to do this in consequence of its being represented to them that many cases of diseased parts, or of malconformation occur, which it would be highly interesting to preserve a record of, but which are lost to the profession because the practitioner in attendance is incapable of making a drawing of appearances which no words can intelligibly describe. It was also considered desirable to endeavour to introduce into this country the art of modelling in coloured wax the parts of the human body in their natural, morbid, or dissected state—the many advantages of which will be manifest to all conversant with such studies. The appeal of the Society to the junior members of the profession has not been made in vain—Mr. J. R. Alcock has sent in a model in coloured wax of a dissected arm, so accurately and beautifully executed, as well entitles him to the gold medal; and large silver medals have been respectively given to Mr. Attenburrow, for his coloured drawing of a dissected arm; and to Mr. Jos. Towne, for a very beautiful small model of a skeleton."

a plaister model of a skeleton, which was considered a meritorious production, and indicative of great ingenuity. It is but justice to add, that in 1827 Mr. Towne received the large gold medal for coloured anatomical models.

I cannot conclude this explanation without expressing my firm persuasion that the profession and the public are both greatly indebted to the society of arts for the encouragement they liberally afford in annually offering premiums to medical and surgical students for models and drawings *made from actual dissection*; to effect which, requires a much more severe study of the parts represented than is usually bestowed when there is no such test, whether the impressions received be vague or comprehensive*. Such exercises, to the surgical student especially, are of important use, as tending to render precise, and to fix impressions otherwise too apt to be indefinite and fugitive; whilst the judicious arrangement of limiting the rewards to those to whom the requisite preliminary study must necessarily prove highly beneficial, is a gratifying instance of the interest which the public takes in the education and useful attainments of the future members of the medical and surgical profession.

I am, Sir, yours, &c.

THOMAS ALCOCK.

COLLEGE OF PHYSICIANS.

Monday, April 19th.

Dr. MATON took the chair this evening, in the absence of the President, who, we presume, was at Windsor in attendance on his Majesty. The meeting was numerously attended, and among the visi-

* "PREMIUMS FOR MEDICAL OR SURGICAL STUDENTS."

For the best coloured anatomical model of a dissected limb, or other part of the human body, in wax or other substance—the Gold Medal.

For the best original drawing (made from actual dissection) of the anatomy of the human body, or of any part thereof, sufficiently full and accurate for the purposes of surgery, such drawing to be not less than the natural size of the parts, by persons under the age of 25—the Silver Medal. For the next in merit—the Silver Isis Medal.

It is required that each model and drawing be accompanied by an outline, with the necessary references to render them intelligible."

tors was Walther, the distinguished German surgeon.

The first paper read by Dr. Hawkins was a letter from Dr. Heberden to Sir Henry Hallford, on the subject of

Small-Pox occurring without any apparent source of infection having existed.

Dr. Heberden having heard that a prisoner in the Penitentiary at Millbank had been affected with small-pox, determined to inquire into the particulars of the case. The circumstances proved to be as follow:—An individual named Garrow, above 37 years of age, had been received into the Penitentiary 14 months previously, and kept, according to the rules of the establishment, without intercourse with any other persons—except the governor, chaplain, surgeon, warden, and task-master, all of whom live within the walls of the prison, though they are not prevented from going out. On the 20th of November Garrow complained of head-ache and fever, for which he was taken to the infirmary: in three days the small-pox appeared in its usual form. When seen by Dr. H. the crusts had just fallen off, and left the skin marked, but not pitted. The eruption had been of the distinct kind, but copious. There had been no case of small-pox in the Penitentiary, and none of the five persons who had access to him were ill. No friends had been admitted to visit Garrow since September, and though he had received a letter from his wife in Scotland, this was after he had begun to sicken; nor did it appear that any instance of small-pox was known to have occurred in her neighbourhood. The disease, however, prevailed in the neighbourhood of Millbank, and Dr. Heberden conjectures that it had been conveyed by the warden or task-master; at the same time, neither of these persons were conscious of having been exposed to it.

Dr. Haygarth and Dr. O'Ryan endeavoured to ascertain the distance to which infection would extend, and were led to think it under half a yard from a subject actually labouring under small-pox.

The above was followed by some *Observations on Sydenham's Theory of Small-Pox*, by Dr. Macmichael.

However familiar the fact, that small-pox and the other exanthematous diseases are infectious may now be, Dr.

Macmichael remarked, that they had long been known before this property, apparently so obvious, was acknowledged. This appeared so remarkable, that it was adduced by the author a few years ago as an argument against the supporters of the "absurd" proposal to abolish the quarantine laws; who held, that where a disease was really contagious, as small-pox, no doubt was ever entertained with regard to the mode of its propagation. Now in exposing the fallacy of this, Dr. Macmichael asserted that Sydenham, discerning as he was, in no part of his writings gave any hint that he thought the disease was communicated from one person to another. This statement, however, Dr. Macmichael thinks ought to be somewhat qualified. In Sydenham's "*Methodus Curandi Febris*," (1666) in the chapter *de Variolis*, among various other matters, the idea of infection is distinctly expressed, for he says the disease will arise "*vel ex ipsis effluviis ex aegrotantium sanguine transmissis*." Yet notwithstanding this close approximation to the truth, Sydenham immediately after lost sight of this view, and involved himself in confused and unsatisfactory refinements. The curious fact of one attack of small-pox guarding the system in general against its recurrence, led Sydenham to reject the doctrine of its being contagious, because in diseases "depending upon any malignant cause," as syphilis, for instance, the same person may be infected again and again. Another argument which he used against admitting it to be contagious, is derived from the suddenness of its attack, and the rapid formation of so large a quantity of purulent matter. In the edition of his works, published in 1685, only four years before his death, all the theoretical doctrines to be found in the earlier copies, are omitted. It was from perusing this, the latest edition which appeared during his life-time, that Dr. Macmichael was led to suppose that Sydenham had made no mention whatever of contagion; and although it appears that he had once entertained the notion, he seems soon to have rejected it as untenable. How strange it appears to us at the present day that any one should witness the spreading of small-pox without suspecting that one person caught it of another! "So often are we on the very threshold of discovery which by some fatality we miss, and

when it is at length made, have only to express our astonishment that we were so marvellously purblind as to overlook it."

Morbid Appearances in Glanders.

On the table were drawings representing some interesting pathological appearances in the horse and ass, presented by Mr. Sewell, assistant professor to the Veterinary College.

The first plate represented hepatization of the lungs of an ass, produced by inoculation from the suppurating hepatized lungs of a glandered horse, that being one of the sources of the disease called glanders. The second represented miliary tubercles resulting from inoculation with the matter of a suppurating tubercle of the lungs of a glandered horse—another, and a more common cause of glanders. Both these experiments had proved fatal within a week. The third plate exhibited the appearance of coalesced tubercles and vomice in the lungs of a horse that died of glanders, being the most common change found in such cases.

On the flowing of Sand under Pressure.

M. HUBER BURNAND, who, about two years ago, described to the Philosophical Society of Geneva an anemometer, in which the force and duration of the wind were ascertained by the quantity of sand which escaped from an aperture, varying in its size with the wind, a notice of which appeared in the *Journal of Science* for last June, was led to institute a series of experiments "*On the Flowing of Sand under Pressure*," which have developed some curious phenomena, and these were discoursed on and exhibited by Mr. Faraday in a very interesting manner this evening.

We owe some of the most splendid ruins in the world, viz. the aqueducts, to the ignorance of the ancients of that law of fluids, that they will always find their level, and it little matters whether the fluid experimented on be water, mercury, or any other melted matter.

As the effect of heat on solids in reducing them to the fluid state has been supposed to consist in the separation of their particles from each other, so as to give them liberty of motion, it might have been imagined, if a like separation were effected by other means, a like phenomenon would result, and so indeed it does in some degree, for fragments of marble and of glass will slip over each other, and shot will flow to a considerable extent; but powdered ice is not water, however finely it may be pulverized, and there is something in fluidity that yet remains recondite. The flowing properties of sand and other bodies not too finely powdered, (that degree of division seems to answer best which will allow the fragments to pass through a sieve containing 33 wires to the inch in one direction, and 45·6 in the other, and the aperture must never be less than ·079 of an inch in diameter,) appear to be of an intermediate kind between those of solids in mass and perfect liquids. Water will flow out of any vessel in which it is contained with a rapidity, and rise to a height proportionate to the head of water in the vessel or the artificial pressure exerted on it; but the flow of sand is always equal in equal times, and it is affected neither by the head above it, nor by any pressure, however great, that may be exerted; neither will sand rise in the opposite leg of a syphon into which it may be poured, as true liquids do, nor will it even displace a fluid, *e.g.* mercury, which may be in the bend of the syphon, or cause it to rise in the opposite leg more than a very minute fraction, to whatever height the sand may be extended. When sand is placed on a level surface, and then raised to an inclined plane, this inclination must be at least 30° before it begins to move, and when it is poured upon a plane, it rises into a conical heap or hillock, having an angle of about 30° , rarely so much as 35° . Shot, peas, &c. give the like results; and it would seem on examination that the heap may be considered a series of cones of greater and greater size overlapping each other, as paper cones might be put over one another, and each supported, not upon the under one, but by its own base; so if the base of the hillock be lessened on any side, a complete layer or cone falls; and hence it would seem that when sand is put into a tube, the bottom of the tube sustains only

the weight of a heap or cone of 30° , and that all the rest, to whatever height the sand may be carried in the tube, is supported by the *sides*, which are in the place of the bases of each successive cone, the apices of which alone are contained within the tube. This will explain the curious fact that no pressure, however great, can increase the rapidity of the flow of sand, because it is transferred to the sides of the vessel, and does not act upon its base, and also why it does not cause the mercury to rise in the syphon, as well as many other like effects which occur in the common arts of life, *e.g.* the hopper of a corn-mill, the brick-maker's pug-mill, &c. &c. To ascertain this still more positively, some ingenious experiments were devised—such as hanging over a very delicate balance a tube with a loose bottom of cork, and its cone of sand in the scale, and then filling the tube with sand (say several pounds), not the least variation was perceived in the index. The same cork, with its sand cone, was also floated on water, and the empty tube held over it, and then sand poured gently in, to the extent of several pounds; and yet it sank not. Thus proving, as did also many other experiments, especially the putting a little sand in a tube fitted with a rammer, and then endeavouring to push it out, but the tube would twist sooner than the sand be moved. A piece of wet paper, also, at the bottom of a long tube, would imprison a column of sand several feet in height; sustaining, by its slight adhesion, merely its little cone, and all the rest being supported, as before, by the vessel's sides. This furthermore gives the principle of a practice which has been by chance adopted, of filling the holes with sand which are made to blast rocks, and which formerly used to be rammed down with much danger, as the powder would occasionally explode from the violence exerted; for it is found that the rock will rather rend than the loose sand be ejected from the hole;—the principle of which is, that the whole force exerted on the arenal column is immediately transferred to the solid sides of the rock itself.

In the library were the improved steel-yards of Messrs. Rowland and Macmillan, a very compact and very ingenious application of compound

levers; Fayrer's new metallic hone; a young alligator, and some beautiful medallions of the late Sir T. Lawrence, modelled by Bailey, and cast by Parker.

COURT OF KING'S BENCH,

WESTMINSTER, APRIL 26.

(Sittings at Nisi Prius, before Lord TENTERDEN and Special Juries.)

MEDICAL GAZETTE.

Saturday, May 1, 1830.

“*Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.*”—CICERO.

ANDERDON v. BURROWS.

WE think it right to place on record the result of this unfortunate business: any observations we might have been inclined to offer were given by anticipation in a former article (see Gazette, Dec. 5th, vol. v. p. 311). We have had an opportunity of perusing certain documents which have not been made public, and we have no hesitation in admitting that the representations on which Dr. Burrows acted were of the strongest possible nature.

The account which follows is taken from the Times: we have given at full length the speech of Sir James Scarlett against the defendant, Mr. Denman's answer, and Lord Tenterden's charge. We cannot think that the Common Sergeant acted judiciously in stating that the amount of damages was a matter of little importance to Dr. Burrows: this probably led the Jury to give more than they would otherwise have done; but the public, who do not look deeply into such matters, will be apt to estimate the magnitude of the offence by the amount of the penalty—and this is very high indeed. That the act was illegal, is apparent and undeniable;—the extent of the difficulties, and peculiarity of the circumstances which led to it, we are not at liberty to disclose.

ANDERDON v. BURROWS AND OTHERS.

This was an action for assaulting and falsely imprisoning the plaintiff.

The Attorney-General, Mr. Brougham, Mr. Adolphus, and Mr. Platt, were engaged for the plaintiff; Mr. Denman, Mr. Law, and Mr. Alderson, for the defendants.

As soon as the pleadings had been opened by Mr. Platt, the counsel conferred together with a view to effect a compromise.

The Attorney-General addressed the Jury. The conversation that had been going on between him and his learned friends had been with a view to arrange matters so as to avoid a public discussion, which could not be pleasant to either party. As, however, his endeavours had been ineffectual, it was now his duty to address them. The plaintiff, Mr. Freeman Anderdon, was the son of a gentleman who had been formerly engaged in mercantile pursuits, and was the partner of Mr. Manning. Mr. Anderdon, the father, who was well known, had acquired a considerable fortune. He had several sons, whom he sent out in the world for the purpose of improving their fortunes, and enabling him to retain a portion of his property for his other children. Mr. Anderdon, sen. was still alive. The plaintiff, Mr. Freeman Anderdon, had been engaged in the business of an underwriter, which business he still carried on through the means of an agent. He had seen a good deal of the world, but he was fond of a retired life, and his habits were those of frugality. He had for some time resided in York-street, Lambeth, and, as he had lived in great retirement, he had not found it necessary to have any establishment of servants. He was a bachelor, and the pursuits which he followed for his own amusement were perfectly innocent and lawful. He had never been suspected by his neighbours or others, who were in the habit of seeing and conversing with him, of being afflicted with that malady under which some portion of mankind unfortunately laboured—namely, insanity. The declaration in this case was for a trespass; and it ascribed to the defendants an endeavour to make him the subject of a lunatic asylum, upon an imputation that he laboured under that disorder. If that imputation were unjust—and he (the Attorney-General) should show that it was—the mode in which the trespass had been committed had greatly aggravated the conduct of the defendants. In the summer months Mr. Anderdon had been accustomed to wear a straw hat, and he generally amused himself by going on the water. He had worn his straw hat during the last sum-

mer, and did not leave it off till the month of November, the time when the transaction in question took place. On the evening of Sunday the 1st of November, two persons came to his gate, and seeing him standing at the door of his house, asked for Mr. Anderdon. He told them that he was that person, and they then took hold of him, and said he must go with them—he was their prisoner. These two persons were the defendants, Thomas Hazard and John Shelly. Mr. Anderdon was, of course, a good deal surprised at the rude attack; but they kept their hold of him, and proceeded to take him in a direction from his own house. He made resistance, and called to his neighbours, who assembled about him and remonstrated with the men for their conduct. At length all the parties were taken to the watchhouse, and when there, one of the defendants was asked his reason for acting as he did. He said he came from Dr. Burrows, and had an authority from that gentleman; he, however, did not produce it at the moment, but on his being requested to show it, he took it out of his pocket and produced it. It was read by one or more of the persons assembled, and it purported to be an authority, signed by Dr. Burrows, an eminent physician, who had had much practice in cases of lunacy. The paper was in these words:—

“By direction of Mr. Oliver and James Anderdon, I hereby authorise the bearers to take charge of Mr. Freeman Anderdon, he being insane, and confine him in his own house.

“G. M. BURROWS, M.D.

“17, Montagu-street,
Russell-square.”

This paper was put into the hands of the constable, who, on perusing it, said it was no authority to the men to confine Mr. Anderdon, and he could not allow him to be confined. On the constable's making this observation, the tide turned against the two men who had dragged him to the watchhouse, and every one present took part with Mr. Anderdon, who had never been suspected of being an insane person. The constable then received a charge from him against the men, and he was liberated. The present action was brought for the assault and imprisonment of his person. That assault and imprisonment Mr. Anderdon conceived to be aggravated by the motive and object in which it had originated. On the next day after this occurred, an inquiry took place before the magistrate at Union Hall office. The magistrate, in the first instance, seemed to think that the inquiry ought not to be merely whether Mr. Anderdon had been assaulted and imprisoned, but whether he was or was not insane. Mr. Anderdon was desirous of giving an opportunity to every person who was acquainted with him and his

habits of life to come forward to speak to that fact. He was willing that every species of evidence should be received. Accordingly, he and his solicitor waited a considerable time, but nobody having come forward to give evidence to justify the defendants' conduct, the magistrate saw that there was no ground for detaining him, and he took his departure. In the course of the day Dr. Burrows went to the police-office, and made a statement to the magistrate, from which it appeared that in acting as he did he had relied on the information of others, and had not himself seen Mr. Anderdon. He therefore was clearly amenable for his conduct. The only circumstance to give any colour to the pretence for confining Mr. Anderdon as a lunatic, was that which the learned counsel would now state to the jury. Mr. Anderdon was a man of fortune; he had many thousand pounds in the hands of Mr. Manning, and he was possessed of other funds. He kept a good account at the banking-house of Messrs. Bosanquet and Company, and his cheques down to the month of October last had never been dishonoured. In the course of that month a draft, which he had drawn in favour of Mr. Young, a picture-dealer, was refused. Mr. Anderdon went to the banker's, who made some apology for dishonouring the draught, and Mr. Anderdon afterwards drew another. That also was refused, and then Mr. Anderdon went again to the banking-house, and, expressing great indignation at this conduct, demanded payment of his balance of 1040l. This was at first refused; but they afterwards promised to pay, on a threat of an action against them. One of the partners in the house of Messrs. Bosanquet and Co. was a brother of Mr. Anderdon. Mr. Anderdon being a prudent man, and having amassed a large sum of money, he determined to invest a considerable part of it in the purchase of pictures, for which he had a very great taste, and by the purchase of which formerly he had very much increased his fortune, most of the pictures being worth considerably more than he had given for them. His brother, however, thought it likely that he might, by his purchases of pictures, squander away that money which he and other relatives expected to be benefitted by at his death. This was the only fact to account for the refusal to honour the draft in favour of Mr. Young, the picture-dealer. On the threat of an action by Mr. Anderdon's attorney, the balance of the account at the banking-house was paid. Now, what would have been Mr. Anderdon's situation if none of his neighbours had been at hand to come to his assistance? He would have been confined in his own house for that night, and, on the next day, Dr. Burrows would have come to him, and the public probably would have known nothing of what had taken place; the re-

mainder of his days would have been buried in silence, and, though he might probably have been treated with kindness, the management of his property and affairs would have been taken from him, and placed in the hands of those of his relations who had instigated the proceeding against him. It was fortunate for him, therefore, that he was within hearing of his neighbours, and that they came to his assistance. They would be brought forward as witnesses to-day, and they would one and all state that they had no reason even to suspect that he was ever afflicted with insanity. The learned counsel was ready to admit that where an individual did labour under an aberration of reason, his friends were justified in interfering to protect him against his own want of discretion, and ought not to be visited with a serious amount of damages in a court of law. If, therefore, the jury should be of opinion that Mr. Anderdon was a fit subject for such a proceeding as that which the defendants had adopted, he (the Attorney-General) would admit that that fact would go a great way towards mitigating the damages, though it would not affect the verdict, because, as there was no medical certificate, the defendants could not in law be justified in what they had done. He was instructed, however, to throw down the gauntlet to his learned friend, and challenge him to prove that Mr. Anderdon was a person who was unfit to be trusted with the management of his affairs. He (the Attorney-General) should shew, by the witnesses whom he should call, that no conduct of Mr. Anderdon's, however eccentric it might appear to some, was to be ascribed to an aberration of reason. His habits had been those of a retired life, and he had been accustomed from his earliest days to economize. If his income at any time amounted to only 250*l.* a year, he made it a rule to live within that sum. That, surely, was no proof of want of prudence or discretion. His taste for pictures he had acquired from his father, who had been a distinguished collector. All his sons had participated in his taste, and the plaintiff, Mr. Freeman Anderdon, in particular. He had undoubtedly expended several thousand pounds in the purchase of pictures, but he had increased his fortune by it. A particular circumstance connected with his purchase of a lot of pictures recently, was stated before the magistrate at Union-Hall. Mr. Young, a picture-dealer, had sold him a picture for 400 guineas. Shortly afterwards, Mr. Young having been asked for the picture by somebody who had seen it, and wished to purchase it, made Mr. Anderdon an offer of 450 guineas for it. That Mr. Anderdon's collection of pictures was valuable there could be no doubt. He (the Attorney-General) had not seen them, and if he had, his judg-

ment would not be worth a farthing; but Mr. Anderdon himself, and others who were judges of them, were convinced that, if he wished to sell them, they would fetch fifteen or twenty thousand pounds. Might he not, then, though he had lived in privacy, have a taste for pictures without being subject to the imputation of being deranged? Then, with respect to his large straw hat, and the imagined singularity of his dress, was the wearing of a straw hat and a particular dress by a man who did not mix in society, to be taken as a proof of aberration of intellect? Mr. Anderdon was very fond of employing himself in his garden, and that circumstance had been relied upon as shewing a singularity of disposition. A singularity it perhaps was, but it was a singularity of good taste, and shewed how much he was attached to innocent pleasures. Many wise men had done the same. He (the Attorney-General) knew one gentleman in particular—he meant his friend Mr. William Harrison—who employed himself in a similar manner, putting on his dress and working in his garden for some hours before he went to attend to his public duties. That gentleman had never been suspected of a want of reason, nor had several of Mr. Anderdon's neighbours, who possessed the same taste for gardening as himself. There was nothing in the history of Mr. Anderdon's life which any one could point to as unnatural, and, until the occurrence in question, no attempt had been made to deprive him of his liberty, nor had any such attempt been made since. No commission of lunacy had been issued against him, nor any step taken to shew that the defendants were justified in what they had done. Mr. Anderdon had led a most inoffensive life, and his neighbours were unanimous in speaking of him as a person in no respect deficient of intellect. He therefore was perfectly ready to go into any inquiry that the defendants might think proper. If any inquiry should be gone into, he (the Attorney-General) should have an opportunity of addressing the jury again; if not, if no evidence should be offered on the part of the defendants, the case would stand thus:—Two of the defendants, by the authority and under the direction of the other, had come to the house and assailed the liberty of one who had a right in every respect to be considered as a free agent, under the horrible pretext that he was a lunatic, and excited in him the fear that he should, if the plan were successful, be imprisoned for life. The two men brought with them a bag, and on one of the persons present expressing his desire to see the contents, it was opened, and found to contain cords, manacles, screws, and other articles. This shewed what the intention of the parties was, and if they had succeeded in carrying this gentleman off, a commission of lu-

nacy would have been issued, and he might never have been heard of again. The idea was revolting to humanity. Unless, therefore, the jury should be satisfied that Mr. Anderdon was a fit subject for this proceeding on the part of the defendants, it was due to themselves and to the public generally not to allow a man, on a suspicion unfounded, and a motive unjust, to be carried off in this manner for the purpose of being confined as a lunatic; and they would, he trusted, mark their sense of the defendant's conduct, by giving the plaintiff an ample and liberal measure of damages.

[Evidence, which our limits prevent us from inserting, was then called to prove the various statements above made. The witnesses all thought that Mr. Anderdon was of sound mind; but the facts elicited by cross-examination will probably be regarded as entitled to more weight than the *opinions* so expressed.]

The *Common Serjeant* then addressed the jury for the defendants. He expressed his regret that the matter had not been arranged without an investigation, which must be painful to persons of the greatest respectability. On the part of Dr. Burrows, however, he was bound to declare that he considered a public investigation as the thing above all others to be desired. No man could be more anxious that his conduct should be considered by a jury, and he came before them in the perfect confidence that he had acted for the best, for the dearest interest of society, and that he was only an object of enmity to persons who basely took advantage of the unfortunate plaintiff to bring him into a court of justice as prosecutor in this case. His learned friend had told the jury, that he (Mr. Denman) was bound to prove that the plaintiff was of unsound mind at the time the assault was committed. He would, however, decline to undertake that task, though, if it were necessary to demonstrate that he was of unsound mind, he should consider the bringing of the present action one of the strongest proofs in support of that proposition. It was a proof not merely that the plaintiff's mind was in a strange unhappy perverted state, but also that he was not a free agent, but the unfortunate and degraded victim of others. Without questioning that the verdict of the jury must be for the plaintiff, all that he was bound to shew was, that Dr. Burrows had acted upon honourable motives, such as a medical man ought to be swayed by, and had been no party to any kind of conspiracy. Dr. Burrows had acted under a terrible responsibility, and he therefore trusted the jury would be of opinion that the smallest possible damages would perfectly satisfy the ends of justice. He did not mean to conceal that the amount of damages would not affect Dr. Burrows in a pecuniary point of view. The jury must have perceived

that he had acted upon the suggestion of others, who would hold him harmless on this occasion; but although those persons would have gladly sacrificed more than the utmost extent of what the jury might give, multiplied a hundred fold, yet if the jury were to give more than the most inconsiderable damages, it would be injurious to the character of a professional gentleman whom it had recently been attempted to ruin by a series of calumnies such as perhaps no individual in his situation ever encountered before. Should the jury give large damages on this occasion, it would hold out a temptation to persons in the plaintiff's unfortunate condition to place themselves in the hands of a class of men whose object was to extract money from the pockets of their families. He was sorry to hear his learned friend state, in compliance with his instructions, that if the plaintiff had not been rescued from the two defendants who obtained possession of his person, he would have been buried from the world, and that all inquiry respecting him would have been stifled. He repelled that imputation in the strongest terms. It was in evidence that for a series of years the plaintiff had been going on in a most extraordinary manner. He had been in the habit of wearing a waterman's coat, not only upon the river but on shore, when he went to be shaved, and on other occasions. It was a striking fact that no intercourse had taken place between him and any member of his family for the last fifteen years. It was not alledged that this state of things had been occasioned by any quarrel with his relations. Supposing there had been some disagreement between him and his brothers, his respectable father was alive, and yet between him and his son there had been no intercourse whatever. So long as twelve or thirteen years ago the plaintiff's estrangement from his family was complete. It was evident that he had lost his caste in society, and kept company with persons unworthy his education and his rank in society. It was stated that the plaintiff was an underwriter, and conducted his business through the medium of an agent. It was remarkable that that agent had not been called to inform the jury how the plaintiff was in the habit of transacting business with him. No proof had been offered of the plaintiff's having exercised his pen, either in the way of business or in communicating with men of his own rank. The jury had heard the plaintiff's witnesses describe him as wearing this extraordinary coat and hat, allowing his beard to grow, living for the last three years in a miserable hut, without a servant to minister to his necessities, and carrying through the streets a flag-basket, such as the wife of a poor tradesman would take to Covent-Garden-market to bring home vegetables in. Did not those circumstances establish a case of suspicion respect-

ing the plaintiff's sanity? Much stress had been laid upon the plaintiff's shrewdness in money matters, but narrow and parsimonious habits were not inconsistent with perversion of intellect. As long as the plaintiff's peculiarities were confined to the circumstances which he had mentioned, his family did not interfere with him, and they took no steps until they had the strongest reason for believing that his property was likely to be dissipated. It was impossible the jury should not have observed that all the witnesses for the plaintiff appeared to have their feelings enlisted in his favour. That was not extraordinary. All restraint was odious to Englishmen, and the bare suspicion that the plaintiff's relations intended to place him under restraint with the view of preventing him from disposing of his property, was sufficient to rouse their feelings in his behalf. Yet, notwithstanding the disinclination of the witnesses to say any thing which might have an unfavourable effect against the prisoner, one of them, Mr. Robson, being asked whether the plaintiff ever dressed like a gentleman, answered, "No, he never did." The screws and other instruments which the two defendants carried with them when they went to seize the plaintiff, were not intended to be resorted to, except in the case of resistance and violent conduct. The certificate had been produced, in which Dr. Burrows stated the plaintiff to be insane, and authorized him to be taken. Dr. Burrows, it was true, had not seen Mr. Anderdon when he signed that certificate; but it was usual to sign such certificates upon the representations of the family of an individual in Mr. Anderdon's situation. Dr. Burrows could not obtain any knowledge of the state of the plaintiff's mind, except by adopting the course to which he resorted, for the plaintiff not being on terms of friendship with his family, would not, of course, allow the doctor to visit him on their part. A candid construction ought to be put upon the conduct of Dr. Burrows. If improprieties were committed by members of the profession to which that gentleman belonged, they were exceptions, and not the rule. Although the plaintiff had been seized by the two defendants, he stated that they had behaved to him with great civility, and that he had no complaint to make against them. That was the assault which the jury had to try. The evidence which had been brought forward had not at all removed the impression of the plaintiff's unsoundness of mind which his conduct created. One of the witnesses described him as being a good gardener; another said that he had maintained a learned conversation with him upon the science of music. He would tell the jury what Mr. Hand, the baker, meant when he said that the plaintiff maintained a sensible conversation respecting music. He meant that he assented to every thing which he

said. This reminded him of an anecdote respecting a friend of his, a distinguished scholar, lately deceased—he meant Dr. Parr. That learned individual once fell into a mistake by supposing that an individual who knew nothing at all about the subject was almost as good a Greek scholar as himself. The mistake occurred in the following manner:—The doctor happened to be placed, at an electioneering dinner, next a man of the lowest class of society, who had not the least knowledge of Greek, and never pretended to it; but he listened quietly to all that Parr said, replying only by frequent nods of the head, and the doctor went away, convinced that he had met with a man who was almost as good a Grecian as himself. Similar acquiescence on the part of the plaintiff had no doubt attained for him the high character for musical knowledge which he had that day received at the hands of Mr. Hand. The only conspiracy in the case was a conspiracy which certain designing persons had formed, in order to obtain possession of the plaintiff's property. Sharpers always abounded in this great metropolis, and their allies were too frequently to be found amongst that class which Johnson had designated in his verse as—

"The fell attorney that roams for prey."

With these observations he would leave the case with the jury. He admitted that the verdict must be against the defendants; but unless he was painfully mistaken, the smallest possible damages would be given.

Lord Tenterden said, that the only question which the jury had to consider was the amount of damages. The conduct of Dr. Burrows, in signing a certificate of the plaintiff's insanity, without having seen him, and sending two persons to secure him, was contrary to law. He was sorry to hear it stated that it was usual for medical practitioners to act in that manner. In estimating the amount of damages, it would be necessary for the jury to consider whether there was probable cause for supposing the plaintiff to have been of unsound mind at the period when the assault was committed. With reference to this point, the plaintiff's singular estrangement, not only from his family, but from persons of his own rank, and his extraordinary mode of dressing and living, were circumstances which should not be overlooked.

The jury then retired, and after being absent three quarters of an hour, returned into court with a verdict for the plaintiff—Damages, 500*l*.

HOSPITAL REPORTS.

GUY'S HOSPITAL.

Case of extensive Abscess in Thigh and around Knee.

BARBARA BOUTON, naturally a stout and healthy woman, 22 years of age, admitted to-day (Dec. 9, 1859.)

When mangling, six weeks ago, she sprained and struck her knee against the machine. It became painful, red, and swollen, and she was obliged to lay up the limb. The pain increased, and a medical man, who was called in, ordered the parts to be poulticed. In a few days the lower half of the thigh, the knee, and upper part of leg, had swelled prodigiously. Ten days before her admission an opening was made just above the inner side of the knee, over the vastus-internus muscle; and she says, that four quarts of matter escaped then and during that day. She had suffered very much previous to this. There has been a very copious discharge since, and she is much weakened by it.

The limb lies on its outer side, bent to a right angle; it cannot be further extended without great pain. There is no redness, but the swelling is considerable. A probe, or rather the stilet of a catheter, can be passed from the wound, upwards, half way up the thigh, and downwards to about three inches below the knee; also a little way towards the ham, backwards. The joint does not appear to be affected. There is no pain, except when touched. Pulse quick and frequent; tongue moist.

10th.—The discharge has been so excessive, that it has literally soaked through the bed on to the floor. A counter opening was made at the upper part of the abscess, half way up the inner side of the thigh. As she lies in bed, this is the most depending part of the abscess.

A large poultice over the parts.

To have a pint of porter daily.

12th.—A second counter-opening has been made at the lowest part, being three or four inches below the inner side of the knee. There are thus two counter-openings, one at each end of the abscess; the limb is placed on the double inclined plane, so that both these openings afford a free exit to the matter. The apparatus is at an angle of about 95°. Patient sleeps well; is not in pain. Bowels open; tongue moist; pulse quick and frequent, very weak.

Ordered.—Continue the porter.

Vini rubri, ʒvi . quotidie.

Mutton chop for lunch.—Meat for dinner.

Habt. Quinina Sulph. gr. ijj . ex Infus.

Rosæ c. cum ʒvi . Acidi Sulph. dil. ter die.

14th.—The limb is easy, and there is a free discharge from both openings. Pulse quick, and very frequent—140 in the minute; tongue moist; face habitually flushed. There is a regular exacerbation every night, from midnight to day-break. The knee to be gradually extended by daily lowering the double inclined plane.

17th.—Says she feels better and stronger. Pulse less frequent, and more powerful; tongue moist; limb lies at an angle of about 125°, not nearly so much swollen as it was; discharge free from both openings, chiefly from the lower one; some matter has gravitated backwards into the ham, which it is proposed shortly to evacuate by another opening.

21st.—Discharge free and much less abundant; limb lies now at about 160°, very easy; her health is improving; appetite good; hectic flushes very trivial.

28th.—Limb is now nearly straight, and the collection of matter in the ham has been evacuated by pressure through the first opening.

9th Jan.—Limb is now quite straight, and she has power to bend or to raise it up (straight) from the bed; there is now very little discharge; a roller is applied from toe to hip, and the splint removed.

Continue the medicines and diet.

9th Feb.—She was discharged quite well.

Case of Acute Abscess in Left Iliac Fossa.

W. Wade, æt. 28, admitted into Naaman's ward, 3d March last, for a bubo in the left groin, which had opened, and become hollow. However, on examination, it appears that three weeks since, without any previous tangible cause, he was seized with headache and pains across his chest; in a week after this, a lump appeared in his left groin, which pointed, and broke four or five days afterwards. A good deal of matter discharged for two or three days, and then ceased. After this he had severe deep pains in the part shooting back to the loins, and preventing both sleep and exercise. He has never had any venereal disease, nor has he received a blow in the part. The general excitement and fever is much more than can be explained by the small hollow abscess in the groin.

Ordered.—Extr. Hyoscyami gr. v. o. n.

Mist. Salinæ et Træ. Calumbæ ʒj . ter die.

11th.—Close examination to-day gave pain on pressure in the left lumbar region, and every where about the lower part of belly and upper thigh on that side. He lies with the thigh semiflexed on the pelvis. There is much distress and great suffering. An indistinct fluctuation was detected deep in the groin.

Cataplasma cerevisiæ, et continuent medicamenta.

15th.—His sufferings have been great. To-day, matter can be felt deep in the groin and left fossa iliaca; tongue white; pulse 120, quick, and somewhat hard. The walls of the abscess appear to extend up as far as the crista ilii, thence across forwards to the pubes, and downwards a little below the line of Poupart's ligament: these parts are exquisitely painful on pressure.

An opening with the lancet was cautiously made by the dresser, about a quarter of an inch below Poupart's ligament, (being the lowest part where matter was felt,) about an inch to the inner side of the femoral vessels, and close to the outer side of the cord. About $\frac{3}{4}$ iv. of good pus immediately gushed out. The opening was then enlarged on a director upwards and outwards, parallel to Poupart's ligament, for the space of an inch, care being taken that no important part was taken up on the director. This dilatation was effected with the probed bistoury. Towards the end of this cut, a large gush of venous blood took place, from the division of some superficial vein. This was stopped by plugging the wound with lint, and a compress.

8, P.M.—Patient had a shivering fit for an hour and a half after the discharge of the matter; he then fell asleep for several hours. The plug was removed, and there came out without pressure $\frac{5}{8}$ j. or $\frac{3}{4}$ vij. of good pus mixed with a few clots of blood, but no active bleeding; he is more free from pain than he has been for the last month; bowels not open to-day; pulse remains quick; tongue white, and face flushed; has perspired abundantly. The finger passed into the wound went into a large cavity, as if over the iliacus muscle, behind the peritoneum.

A large poultice over the wound.

16th.—Throughout the night has been in a state of delirium, which has not yet subsided. Pulse 124, quick; tongue dry and brown; face flushed; skin hot; bowels open. Plug removed, and about $\frac{3}{4}$ iv. of thin matter let out; this was followed by a smart hæmorrhage, which was arrested as before, by means of a plug and compress.

Ordered—Calomel. et Opii aa. gr. ij. statim.

Træ. Hyoscyami $\frac{3}{4}$ ss. et Mist. Efferves. 4tis horis.

17th.—Is more calm to-day; tongue dry; pulse quick, 110; bowels much relaxed, stools being thin and bilious; has pain on pressure of the epigastrium; is troubled with a cough, which throws out the plug, and renews the bleeding. This morning there came a full gush of venous blood, which was stopped as at first, leaving a space for the exit of matter at the lower and inner angle of the wound.

Calomel. et Opii. aa. gr. iss. h. somni, et Pergat, &c.

18th.—Had a severe shivering this morning, and now (11 A.M.) is perspiring strongly; pulse 132, small; tongue dry and rather brown; is very thirsty; no pain in the abscess; the plug being removed, there followed a little sanious matter, of most offensive odour: it was doubted whether this was the smell of putrid blood or of fæculent matter; bleeding returned, and the wound was again plugged; bowels still relaxed.

Contin. Cal. et Opium h. s. et Mistur. Efferves.

19th.—This morning the plug has worked out into the poultice, and no bleeding has recurred; an ounce of fetid sanious matter with a clot of blood were pressed out of the abscess; pulse 118, small and weak; countenance more tranquil; tongue not so dry; has had two rigors this morning, and is now perspiring greatly; bowels still loose.

The patient remained pretty well till 4, P.M. at which time he coughed somewhat violently; bleeding from the wound came on, and he lost about half a pint of blood. When the dresser of the week arrived, the bleeding had ceased. Now (8 P.M.) he is much depressed; pulse scarcely felt at the wrist; is quite delirious, and disposed to get out of bed if not restrained; complains of severe pains and aches all over him. 10 P.M. has just had another rigor, and is bedewed with sweat; pulse 160, very feeble; tongue much coated, but not dry; countenance somewhat wild; no more hæmorrhage.

Arrow-root flavoured with wine to be given from time to time.

Calomel. et Opii aa. gr. j. h. s. et pergat.

20th.—Has had a moaning restless night, and is scarcely sensible now. Pulse 132, small and feeble; tongue coated; skin hot; features shrunk; is in general pain; not more than a table-spoonful of the same fetid discharge from the wound. At two o'clock he lost $\frac{5}{8}$ j. or $\frac{3}{4}$ ij. of blood. The finger passed into the wound could arrest the hæmorrhage by pressing the skin against the thumb. The plug was renewed, and soon after he had another severe rigor.

10 P.M.—Is less rational, and disposed to be very unquiet; bowels relaxed; thin clayey stools; tongue coated and dry; pulse very feeble and frequent. The skin around the wound looks shining and smooth, and on pressure is tender; no more bleeding.

21st.—He went on in this state through the night, rambling very much, and gradually sinking. He died at 9 o'clock this morning.

The body was inspected 28 hours afterwards.

Underneath the fascia iliaca, and over the psoas and iliacus muscles, penetrating a little into their substance, was found the abscess. It extended up along the

psoas, not quite to its origin; downwards it dipped into the pelvis by the side of the bladder, behind the pubes; and over the pubes it passed deeply down for three or four inches, in the direction of the psoas and iliacus muscles towards the trochanter minor. No bone could be felt denuded any where, nor was there any apparent disease of spine to which this abscess might have been ascribed.

The abscess contained a small quantity of purulent ichor, with a few coagula. The parts which formed its walls were livid, and easily lacerable, as were the iliacus and psoæ muscles especially. The external pudic vein had crossed the abscess, and had been divided just before it entered the femoral vein. The last vessel and accompanying artery were much raised up by the abscess, and were involved in the disorganization and livid slough around: their coats were entire. The inner surface of the artery was more injected than usual; that of the vein was natural. There was a string of fibrin in the vein.

ST. THOMAS'S HOSPITAL.

Fracture of the Spine, with Paralysis—Favourable termination.

JOSEPH STOCKWELL, 15 years of age, admitted into Abraham's Ward on the 24th of November, under the care of Mr. Green. He stated that a cask fell on him from a height, which struck him down and stunned him. At the time of his admission, which was shortly afterwards, he had recovered from the stupor and was then perfectly sensible, but could not tell where he had received the blow; that a cask had fallen upon him, was the only account he could give. He complained of a good deal of pain between the shoulders, with tenderness on pressure, and pains shooting from this part through the chest and towards the axilla; all power of voluntary motion was lost in the lower extremities, but a sense of numbness existed in them, and likewise over the abdomen; motion in his upper extremities continued perfect, and sensation but little or not at all affected; priapism and loss of power over his bladder were present, and his ribs moved but very slightly during respiration, which was the result only of the expansion of the lungs, but he breathed easily by the diaphragm; and he had a slight cough, which produced pain in the epigastric region when it occurred. On examination of the bony column, an evident depression was detected just below the spinous process of the second dorsal vertebra, which was the only irregularity then perceived. He was ordered to have ten leeches to the back, and to take ten drops of tincture of henbane in an ounce and a half of saline mixture,

every six hours. The catheter to be used. On the following day the pain in the axilla had increased; the urine was tested and found acid, as was likewise that which was drawn off on the preceding evening. Priapism somewhat less. On a more minute examination, the spinous process of the third dorsal vertebra was observed to be moveable, and Mr. Green was of opinion that the body of the bone was fractured. After a consultation, it was determined not to perform the operation for trephining, but to lay the patient upon a fracture-bed, with a trap-door so constructed that he might be examined without moving him, which was done towards the evening. In consequence of not having had an evacuation per anum, he was ordered an enema, and twenty more leeches to the spine. Pulse about 100, and compressible.

26th.—Has slept well, and is quite free from pain; sensation more perfect in his lower extremities, and also over the abdomen; has observed a slight motion in his legs; bowels have acted several times, and are under the control of the will; when he attempts to pass his urine, he says he feels it rise to within an inch of the orifice of the urethra.

31st.—His pulse is natural, and he says he feels himself quite easy; is able to move his left leg a good deal, but the motion of the right is much more limited.

Dec. 5th.—He is going on well, and the urine continues acid. On the 2d there appeared a little excitement, and he had occasional priapism.

10th, 15th, and 23d.—He is now able to move his right leg very considerably; on the 10th the priapism had entirely subsided, and on the 15th there appeared to be a little action in the intercostal muscles, which have now regained more of their habitual motion.

April 12th.—From this time he was confined to bed until he had remained there about twelve weeks, when he was allowed to get up. The healthy functions were then more fully established; he could not, however, bear the weight of his body on the left lower extremity, but he walked with the assistance of crutches, which he continued to use, gradually bearing more and more upon his feet. After having used them rather more than six weeks, he left them off, and is now (April 12th) able to walk as well as ever with the left leg, but limps with the other. He says he feels a stiffness in the hip and knee-joints, and is not able to flex and extend the ankle-joint as usual, consequently he walks flat-footed on that side. On tracing the spinous processes of the dorsal vertebrae, there is a slight diverging from the natural line of the projection of the third: the irregularity inclines to the right side.

CHARLESTON HOSPITAL.

Observations on Pyroligneous Acid in Gangrene.

By THOMAS Y. SIMONS, M.D.

IN a late number of the American Journal of the Medical Sciences, the conductors have done me the honour of taking notice of my successful use of the pyroligneous acid, in sphacelus, and phagædonic ulcers. As I regard this remedy of great value to the surgeon, and have since 1824 used it with uniform success and satisfaction, I am induced to make a few remarks on the manner of using it, and to relate three cases, which were considered so desperate as to leave little hope of recovery, in which it proved efficacious. I beg leave to premise that I never read or heard of the acid being used for any other purpose than as an antiseptic in preserving meat, antecedent to my employing it, and I was led to use it from the fact of my believing that if it was so powerful on dead matter, it would be much more efficient when it was aided by the vital principle. Although long convinced of its value, I could not induce medical gentlemen in general to try it, they believing other established antiseptic remedies equally salutary, if not superior, until the cases which I shall presently relate were brought so strikingly to their view.

There are two kinds of pyroligneous acid found in the apothecaries' shops; one is transparent, and when agitated, shews small crystals floating in it; the other is dark and smoky; both have the empyreumatic odour. The former is the kind I use, and is by far the best.

When I first used this acid, I diluted it with six times its quantity of water; but since I have employed it diluted with equal parts of water, gradually diluting as the sore assumes a healthy appearance, until it becomes as weak as one twenty-fourth. It should always create a smarting sensation. The manner of applying it is to put over the ulcer some lint, which is to be kept constantly wet, and changed two or three times during the day, according to circumstances. The ulcer ultimately assumes red granulations resembling the inside of the pomegranate. If the acid be too strong, it will make it turn white, and assume the appearance of a slough.

CASE I.—William Smith was brought into the hospital, May 9th, suffering under mania a potu. After he was relieved of this disease, I observed in the anterior part of his right leg, a dark spot occupying about two-thirds, where a blister had been applied, as he informed me, previous to his entering the hospital. The commencement of mortification was evident, and I ordered him at

first bark poultice, not having at that time the pyroligneous acid in the hospital, and the following constitutional treatment:—

R Sulph. Quinine, iv. grains; Aq. Fontana, ℥viii.; Acid Sulphuric, xx. gtt. Two table-spoonsful to be given every two hours during the day; at night he was given two grains of opium and five grains of camphor. He was allowed a pint of porter and a meat diet.

This course was continued for two days, but without checking the gangrene; indeed it was so rapidly advancing, that several physicians were of opinion that immediate amputation would be necessary. Having, however, obtained the pyroligneous acid, I resolved to use it first; accordingly, I made free longitudinal and transverse incisions to the full depth of the gangrened portion, and then water and pyroligneous acid, in equal portions, were applied constantly in the manner already described, and the constitutional treatment was continued. In twenty-four hours a line of demarcation was formed, and in twenty-four hours more the gangrenous portion was separating from the healthy part. In seven days the whole of the gangrene was removed, and a healthy surface was presented. The acid giving pain was diluted to one-sixth, and ultimately to one twelfth; and on the 26th September the patient was dismissed cured. The length of time of healing was produced, I think, from my omitting the acid after healthy granulations were formed, and using the adhesive straps.

CASE II.—Edward Campbell, from St. John's, Berkely, South Carolina, came into the hospital on the 24th of August. He said that about Christmas he got a bruise on his shin, which he neglected. It was afterwards quacked with by some old woman in the parish, until it assumed the character which I shall now describe. There was an extensive sloughing ulcer, deep, irregular, and jagged, extending from the lower portion of the tibia two-thirds upwards, exposing a part of the bone which was carious, and the tendon of the extensor longus digitorum pedis. The fætor from the ulcer was so great as to induce me to remove the patient to a place separate from the other inmates of the hospital. My patient was extremely emaciated and hectic, and I observed to the medical gentlemen and students who were present, that I had no hopes of saving the limb, but that it was desirable to place him under constitutional treatment, so that I might improve the conservative principle of the system (to adopt Sir G. Blane's language), previous to my amputating the leg, and that I would apply the

strongest solution of the acid merely to correct the fætor. The treatment was—

R Sulph. Quinine, vi. grains; Acid Sulph. xx. gts.; Aq. Fontana, ℥viij. Two table-spoonsful every two hours during the day; at night two grains of opium, to lessen irritation and procure sleep, which he had not enjoyed for some months. The diet was a pint of porter daily and beef-steak.

In two days the fætor of the ulcer was overcome. In ten days it was much improved, and I took away a large piece of bone which had exfoliated from the tibia. In four days more I removed with the knife a considerable slough of the tendon of the extensor longus digitorum pedis. From this time the ulcer began to improve rapidly, and healthy granulations appeared. This course was persevered in for some time with continued improvement of the leg, when my patient suffered it to be kept hanging down, causing the blood to determine and stagnate at the ulcer, when an extensive sloughing and gangrene commenced (the acid having then been omitted), which continued for three days, until the pure acid (the brown and smoky one having been sent me by the apothecary, which proved inert) was obtained, which checked its progress in twenty-four hours, and removed it altogether in a week. The patient was made to keep his leg elevated, and the acid was continued until Nov. 7th, at which time the leg had almost healed, and the acid was omitted.

CASE III.—Charles Belton was brought into the hospital on the 13th of September, suffering from the effects of intemperance. I observed a red suffusion over his left thumb, with considerable tumefaction; he complained of its giving him great pain; I ordered a poultice of bread and milk. This was continued for three days, when the inflammation increased, became more painful and tumefied; a fluctuation was felt as if there was matter, and there appeared to be a disposition to point over the second articulation of the thumb. I made a free incision, when very little matter escaped, but a great quantity of blood. On the next morning, I was informed that upwards of two pounds of blood had come from the wound, although I regarded this quantity as exaggerated. I found, upon examination, the wound had all the appearances of fungus hæmatodes. It spread out on each side of the incision like a mushroom, was fungous, very vascular, and oozing blood at every part. So formidable an appearance, in so short a time, left little hopes of relief but in removing the diseased part, which remedy is more than equivocal as regards success. It was, however, suggested to me by a medical friend, that as the pyroligneous acid had proved so

valuable and efficacious in the other cases, whether it would not be worthy of a trial in a disease which has generally defied the power of remedial agents*. I readily consented, but with no hopes of success. The acid was applied in its strongest form, which in two days checked the hæmorrhagic tendency. In fifteen days the fungous character of the wound was subdued, when lunar caustic and adhesive straps were applied, which completed the cure on the 25th of October.

During the prevalence of yellow fever in Charleston, in 1824, I gave the acid much diluted internally, during the black vomit stage, but with no benefit. I have no doubt it would prove salutary in putrid sore throats, as a gargle, and it would be worthy of trial in cancer; in neither of which have I yet used it.

I have drawn up these cases and observations from a conscientious conviction that a proper use of the pyroligneous acid will be the cause of saving to many human beings limbs which otherwise would be cut off, and with the anxious hope that its use among surgeons may become general.

Charleston, S. C. Nov. 1829.

* I am not aware that there is another case of cure of this dreadful malady on record.

BOOKS RECEIVED FOR REVIEW.

THE following books having been mislaid, were omitted in a former list:—

The Influence of Climate in the Prevention and Cure of Chronic Diseases, more particularly of the Chest and Digestive Organs. By James Clark, M.D. The Second Edition.

A Practical Essay on the Disease generally known under the denomination of Delirium Tremens. By Andrew Blake, M.D.

A Letter to William Lawrence, Esq. F.R.S. on the Nature and Causes of Intellectual Life and the Mind. By William Addison.

An Experimental Inquiry into the Laws which regulate the Phenomena of Organic and Animal Life. By G. Calvert Holland, M.D.

ERRATUM.

In the reference to Mr. Liston's paper in our last No., p. 101, instead of "nineteenth volume of the Transactions of the Edinburgh Medical and Chirurgical Society," read "nineteenth volume of the *Edinburgh Medical and Surgical Journal*."

LECTURES ON SURGERY,

Delivered at St. Bartholomew's Hospital,

BY WILLIAM LAWRENCE, F.R.S.

— Nov 17

LECTURE XXXIX.

Leprous Encrustations—Tubercula—Cancer of the Skin—Chimney-sweep's Cancer—Subcutaneous Tubercle—Warts—Corns—Bunyon.

I HAVE a specimen here, gentlemen, which Mr. Langstaff has been kind enough to bring me, of a scaly encrustation formed in a leprous eruption. This is an example of that kind of mass of scaly deposit that sometimes take place in affections of this kind: it was taken from a young woman, about 20 or 21 years of age. Here the groups are aggregated into large masses; on the opposite side are exhibited what we may call young scales. Thus you see the extent to which the affection will go when no means are taken to keep the surface of the skin clear from these cutaneous encrustations.

Tubercula—Cancer of the Skin.

The skin, gentlemen, is sometimes subject to cancer, and this affection is arranged under the order *tubercula*, by the cutaneous nosologists, because cancerous disease begins in the skin with a small indurated enlargement called a tubercle. In fact, cancer of the skin goes through the same two successive changes which I have had occasion to describe to you in speaking of the affection generally. There are, in the first place, induration and enlargement, or the schirrous condition; and there is subsequently the state of ulceration. All parts of the skin are not equally liable to cancer. The integuments of the face, and perhaps particularly those of the eyelids, are the most so. We occasionally see it on the external organs of generation, in both sexes; sometimes on the hands. These are the parts most commonly

the seat of cancer externally. The scrotum, in the male subject, is liable to a peculiar kind of cancer, from certain local causes which I shall have occasion to mention to you hereafter.

When cancer affects the integuments of the face in the first instance, it begins with a small induration and enlargement at a certain spot, which may be called a *tubercle*; and which the patient supposes to be a wart. It is uninfamed, and of the colour of the natural skin, and it is not particularly sensible. In this state the affection may remain for a considerable length of time, though it sooner or later ulcerates; and the ulcer which is formed on this tubercular enlargement of the skin does not penetrate very deeply—does not assume any very unfavourable appearance. It secretes a matter which forms a thin brownish encrustation over the part, and, being exposed to the air, a kind of thin skin, or crust, forms over the ulcer; and in this state the affection goes on for a long time, without the patient paying much attention to it—the tubercle not being considerable in size, and the ulceration formed on it being also of trifling magnitude. The disease, however, gradually advances, and ultimately an ulcer of considerable size is formed. In this state, we find that the margin of the sore is elevated, presenting more or less of a tubercular character, but preserving nearly the same colour with that of the sound integuments. There is no great excavation formed by the sore, and the secretion that takes place from it does not seem to possess any acrid or offensive properties; and, in fact, in this form the disease goes on without any very rapid increase or very serious alteration for a considerable number of years. It is particularly characterized by slowness of development and progress, and, in the majority of instances, it does not affect the absorbent glands in the way that cancer does when it takes place in other parts—in the female breast, for instance.

Perhaps we see this affection more fre-

quently in the eyelids than in other parts of the face. In the month of December, 1825, I removed the principal part of the lower eyelid of a gentleman, on account of this affection; and at that time the disease had already existed about five years, and even then it had not completely destroyed the whole of the inferior palpebra. It consisted of a tubercular induration of the skin. The tubercle of which this enlargement consisted, had externally the same colour and appearance as the sound skin, having over it a few red and slightly varicose vessels. The affected eyelid might be said to be about twice the natural thickness; and on the surface of this enlargement ulceration had taken place, which began at the internal angle of the eye, and had gradually eaten its way towards the external angle: it began in the exterior of the eyelid, and did not extend so much on the mucous as on the external surface. Indeed the disease seemed to be essentially an affection of the integuments of the eyelid, and not of the mucons membrane. This affection had given the gentleman no great inconvenience—had not been attended with much pain; but the sharp edge of the eyelid, where it had been ulcerated, came in contact with the globe of the eye, and had occasionally irritated it so as to produce a good deal of inconvenience. Various local applications had been tried in this case, but none of them had any effect, and I therefore extirpated the parts. To do this completely, it was necessary to take away nearly the whole of the inferior palpebra, including the inferior punctum lachrymale, and a considerable portion of the inferior lachrymal duct. The wound healed very favourably, and the gentleman now, at the distance of four years from the time of the operation, remains perfectly well; the part is quite sound, and no inconvenience has occurred in this instance from the removal of the inferior punctum.

In the course of last summer I had a patient in this hospital, about forty years of age, in whom a similar affection existed on the left side of the nose, occupying that part of the cheek which is towards the ala nasi. It consisted of an ulcer about one inch and a half in length, and about half or three quarters of an inch in breadth; the margin of which was indurated and irregularly elevated; the sore was not very deep; it had somewhat of a red surface, without any appearance of granulation, and produced a thin discharge, not in very great quantity. The ulceration in this individual had existed about six years. I extirpated the parts, and took away the whole of them, by cutting a short distance from the seat of the disease. The wound healed very favourably, and I have heard nothing of the patient since. In this instance I had

an opportunity of examining the state of the affected skin;—on comparing the depth of the ulcer with the thickness of the skin, one would have supposed that this had been entirely destroyed by the ulcerative process, because there was an elevated margin of the skin surrounding the ulcer; but when I came to make a section, I found that the texture of the skin remained at the base of the ulcer; there was, as it were, a thickened stratum of cutis. One should say, that the natural texture of the skin was rather thickened, and it formed a sort of fibrous structure shooting towards the ulcerated surface: it was the kind of skin usually presented in these cases. In this instance there was no affection of the absorbent glands. The cases that I have now mentioned to you shew that, although these complaints are called cancerous, they admit, to a certain extent, of cure. It seemed that here the affection had commenced upon the ala nasi, and a considerable part of it had been destroyed by the ulcerative process, and the part so destroyed had cicatrized; and, indeed, while the patient was in the hospital, a disposition to cicatrization seemed to prevail on the aspect of the ulcer towards the nose;—but in other parts it seemed to spread so, that there appeared little encouragement to attempt a cure by any means save that of operation.

I remember seeing an instance where this affection took place on both the eyelids—where, in fact, it destroyed the whole of both eyelids, and had extended partially into the orbit, close to the globe of the eye; which last, however, had not become affected, except through exposure to the air. The disease had here existed seventeen years; and even then the absorbent glands were not diseased.

The great advantage which is often derived from arsenical applications to that description of ulceration which I have mentioned to you under the name of lupus, has led to their use in some of these cancerous ulcers of the face, but they are not here equally efficacious; nor, in fact, is their employment equally safe; for you sometimes produce a degree of irritation in the sores which increases the mischief, and occasions the affection to spread more rapidly.

For this reason, it is necessary that you should carefully distinguish between ulcerations of the face of a cancerous character and those that belong to the head of lupus. The tubercle from which cancer commences is hard; it is uninfamed—that is, it has the same colour as the natural integument. The tubercle of lupus is softer, and of a bright red colour. The cancerous tubercle is single—that is, the affection is confined to one spot. In lupus there are generally two or more spots of skin affected. The margin of the ulceration in cancer is tuberculated; it

is hard, but retains the same colour as the surrounding integument; the ulceration generally presents a smooth red surface, and is particularly characterized by its slow progress; it does not eat deeply, nor does it destroy the parts rapidly. In lupus, the edge of the ulceration is of a bright red; the skin surrounding the sore is of the same colour; the ulcerated surface itself is generally yellow, something like the phagedenic sore, and the destructive process extends so rapidly that it will destroy the ala of the nose, or any other part, within a very short time.

We sometimes see ulceration of a cancerous nature affecting the external organs of generation in the female—affecting either a part of the integument or a part of the thinner covering which lines the external cavity of those parts, and sometimes it occupies both. It is here of importance to distinguish the affection, because such ulcers are liable to be mistaken for venereal sores, and, under this mistake, to be treated by means which are not capable of rendering any service in cases of cancer. The sore in these cases—I have not seen here any thing like tubercle—is generally deep, there is considerable excavation, it has a red appearance, like raw flesh, the margin of the sore forms a kind of sharp-cut edge, and the secretion is a thin ichor;—great pain is experienced in the part. I have generally observed, in these cases, that the glands in the groin were affected. The disease is slower in its progress than venereal ulceration, at the same time it proceeds more rapidly than cancerous ulceration seated on the face.

The only treatment that I have found of any advantage in these instances, has been the palliative or soothing; soft poultices applied to the part, opiate applications, such as the solution of opium in water, or Mr. Battley's liquor opii sedativus, and the administration of opium internally, to lull the pain.

I had lately under my care a lady who had a cancerous ulceration of this sort. It was situated in the inferior edge of the mons veneris; it was bounded below by the upper part of the clitoris and nymphæ. It had existed about two years when I first saw her, and there was an excavation large enough to hold the end of the thumb under the mons veneris. The surface of the sore was rather foul and unhealthy; there were some parts of it had a kind of sloughy appearance, presenting an ash-coloured surface. The sore had rather an irritated appearance. In truth, upon examination, I found that, for some time, a succession of stimulating and heating applications had been made to this sore, under which the lady had experienced considerable aggravation of suffering, and owing to which, probably, the

sore had got into an unhealthy state. Caustic, mercurial fumigation, and means of that kind had been applied to this sore, under the idea, probably, that it possessed something of a venereal character. When these means were laid aside, and the soothing plan was adopted, the painful state of the sore went off, and the suffering altogether was materially alleviated. In this instance, the absorbent glands of the groin on both sides were enlarged and indurated, but in other respects the lady appeared in good health. She had not lost flesh, she had a good appetite, and the other functions were well performed. She continued under my care some time, and when I last saw her she came to me apparently in good health, and looked extremely well. The ulceration, at that time, had considerably increased; the excavation was so large that it would have held a large walnut, but yet it had a tolerably clean appearance. The indurated glands of the groin on the right side had suppurated, but had not formed an external ulcer, though there were small openings like pin-holes in numerous places, through which a copious discharge issued. After some time, I was rather surprised by hearing that the lady was suddenly taken ill; I could not exactly make out in what way, but in fact she died within a fortnight of the time of my last seeing her.

I have not seen any instance of cancerous ulceration occurring about the external organs of generation of the female in which I have deemed it advisable to remove the parts by operation. In the present instance, the situation was such as would have admitted of removal provided the glands of the groin had not been affected, but the affection of those glands seemed to me entirely to preclude all idea of extirpation.

We sometimes see an affection commencing on the skin of the hand, probably deriving its origin from some of those direct irritations to which the hands are liable, proceeding to indurated ulcerations and a kind of warty state of the skin, and this going into a condition which I cannot describe by any other name except that of cancer, and in fact possessing in every respect the intractable nature and unfavourable character that belongs to that disease.

I had some time ago under my care in this hospital a patient who had an affection of this kind in the hand. He was 55 years of age. He came from Sussex, where he lived as a labourer, and he enjoyed good health. He had warts over different parts of the hand and fore arm; and one of these, which was situated on the back of the thumb, had become troublesome, and either under the care of some old woman or some practitioner—I forget which—a succession of caustic and acrid applications had been made to it, by which the part became painful, and ulti-

mately spread and extended into a very formidable disease. When he came to the hospital, he had the whole of the integuments covering the back of the first joint of the thumb and extending over the metacarpal bone of the fore finger, considerably enlarged, in a tuberculated state, inflamed, bright red, and ulcerated at various points. In this inflamed and tuberculated mass there were several ulcerative excavations going deep into the parts, and giving issue to a thin, fetid, ichorous discharge. In other parts, this enlarged substance presented merely the character of a wart, that is, an irregular rough surface, which seemed to be partly ulcerated. The margin of the diseased skin was enlarged and tuberculated, and the affection appeared to extend by the gradual sloughing and subsequent ulceration of those tubercles which formed in the circumference of the diseased parts. The character of the discharge in this instance particularly pointed out the nature of the affection: although the patient was healthy, and there was no reason why any common ulcer should not produce natural healthy pus, yet that which flowed from this sore was of a watery consistence, a light yellow appearance, and very fetid. It did not partake in any degree of the characters that belong to the discharge from healthy ulceration. There was considerable enlargement of the glands in the axilla; they formed a tumor about the size of a pigeon's egg, which was soft to the feel. When inquiry was made respecting this tumor, he said that it had existed long before the disease had assumed the appearance I have described, as presented by the thumb. This was a point, of course, that was particularly investigated, because it involved the question, whether it would be right to remove the part by amputation or not. If the swelling in the axilla had been regarded as a cancerous affection of the glands situated there, it might, perhaps, have constituted an objection to the operation; but it was found that the disease had existed there previous to the complaint on the hand, of course it would not appear in the same light. The swelling in the axillary glands was soft; it was not hard to the feel, and therefore it was considered that possibly the account the man gave might be right, and that it had existed there longer than the disease in the hand. I had resolved upon performing the operation in this case, the complaint being decidedly cancerous; but it was suggested that some local means might be tried previous to the operation, and in fact cinnabar fumigation was mentioned. This was tried, and the effect was a great aggravation of the inflammation of the skin, and an attack of erysipelas in the hand and fore arm, which was rather serious. When that was got rid of, I amputated the hand, removing the part at the joint of the wrist,

The wound healed very well;—however, the fore arm for a length of time remained swelled, and was the subject of constant attacks of inflammation, so that it was necessary to apply leeches, and adopt various other measures; and we did not think the man in a fit state to go out of the hospital until several weeks after the performance of the operation,—which took place in July 1827. In March 1828 he returned to the hospital with a great increase of the swelling in the axilla. It had now acquired the size of a small apple; it was hard, and the integument adhered to it closely, though it was moveable on the parts on which it rested. There could now be no doubt that this was a cancerous affection of the axillary glands, and it was thought expedient to give the patient a chance of recovery by removing the disease. I accordingly extirpated the glands, which adhered so closely to the great vessels that about one inch and a half of the axillary artery was laid bare by the dissection. The parts healed upon favourably, and the patient left the hospital soon after the operation. However, in no long period he returned again, and he ultimately died from a recurrence of the disease in the axilla.

You see, therefore, that although cancer of the skin may present appearances somewhat different from that which we see when it takes place in the mammary glands and in some other organs, (in fact, we should expect from the differences of texture, that cancerous disease would present some modifications,) yet that in its essential nature, and in its destructive character, so far as it regards the texture in which it is developed, and its effect on the life of the individual, it is exactly similar to that disease elsewhere.

Chimney-Sweep's Cancer.

I have mentioned that in the *scrotum* there is a peculiar cancerous disease occurring in certain individuals; the affection I allude to is, the *chimney-sweep's cancer*. This is an interesting kind of affection, because it shews that a malignant disease, in all its principal features very closely resembling cancer, may be produced in persons, otherwise healthy, simply by local irritation; for chimney-sweep's cancer is the direct result of the irritation of soot lodging in the rugae of the *scrotum*. This affection, however, does not occur in what are commonly called "climbing boys,"—it is not in children who commonly perform the office of cleaning chimneys; it takes place in adults,—those adults who, in following this avocation, have their skin as much in contact with and as much liable to be irritated by soot as climbing children. It is very uncommon, and perhaps there is hardly an instance known, of the affection occurring before the age of pu-

berty, and indeed it very rarely occurs under the age of thirty. The disease commences in the scrotum by the formation of an indurated enlargement of the integuments, like a wart, and which in common language, and usually by persons who follow that calling, is denominated a *soot wart*. There is tubercular enlargement and induration of a portion of the integument of the scrotum. In this state the disease often remains for a considerable length of time. The cuticle may be separated, and a little exudation may take place from the part, and form an encrustation upon the surface of the wart, which may be picked off or removed accidentally. However, sooner or later this part ulcerates, the principal characters of the ulceration corresponding to those of cancerous disease, that is, there is a deep excavation, a thickened base, thickened edges, and very commonly an elevated and everted margin, while the ulceration thus produced gives rise to a very copious and fœtid ichorous discharge. Sometimes the affection consists not so much of a state of ulceration as in a warty, or rather a fungoid excrescence, of the affected part,—what we should call a soft vascular kind of wart, which produces the same kind of offensive ichorous discharge as the ulcer. Whether the affection take place in one or other of these forms, it will extend over the whole scrotum, and gradually pass to the perineum. After it has lasted for a certain time, it will become extended to the testes, and the glands in the groin will become enlarged and indurated, and, if the disease go on, will pass into a state of ulceration. The affection is attended with very severe pain, and in that respect it resembles other cancerous diseases. The persons in whom it occurs generally exhibit marks of an unhealthy constitution: they are thin and emaciated, and they have a peculiarly dark, sallow, and earthy appearance of the skin; and it has been often observed that the cutaneous perspiration generally has a very offensive smell. The progress of this disease, by its local effects, and the serious influence it produces on the constitution, ultimately destroys the individual. I am not aware, however, whether in this, as in many other forms of cancer, the internal organs of the body become affected. There is a short account of the disease, published by Mr. Pott, in which, however, he does not advert to this circumstance at all.

No local remedies, and no internal medicines, have any effect whatever in arresting this complaint. In that respect it corresponds with cancer generally. Local remedies may soothe: the application of opium, for example, may lessen the pain, and other applications may diminish or relieve the fœtor of the discharge; but I am fain to confess to you that we have not the power, either by internal medicines or local applica-

tions, to prevent the destructive progress of the disease, although we may relieve or lessen particular symptoms by internal or external means. In fact, the only effectual mode of treatment in these cases is extirpation; and whenever the disease can be completely removed—whenever we can carry the incision beyond the parts actually affected, so as to cut into parts sound in their structure, we may remove the disease with great confidence in the efficacy of the proceeding. If we leave behind any parts that have become indurated, and still more any parts that have become ulcerated, we cannot be surprised if the disease should re-appear. But if the disease be so circumstanced that we can take away all the parts indurated or ulcerated, so that we can carry the incision into parts completely sound, then the operation of extirpation is a complete, a safe, and an effectual remedy. It does not matter how far the disease may have extended in the integuments: if, for instance, it should involve all the integuments of the scrotum or perineum, we may freely take away the part; for although we may denude the testes and the penis, yet the surrounding integuments are drawn together when cicatrization takes place, so as to cover up the parts that have been thus exposed.

It may be a question how far the operation ought to be performed if the testis be involved in the disease. Now it appears to me that the disease does not readily spread to the testes;—at least you find the cellular membrane, intervening between the ulceration and the testicles, so far thickened, that you cannot move it on them; so that you might judge that they were involved in the disease; and yet you find in such instances that the testes, though apparently implicated, are perfectly sound. I remember an instance in which I took out both testes, the spermatic cords being healthy; they were completely imbedded in the affection of the scrotum; but when the testes came to be cut into, they proved to be quite sound. The mere circumstance of the diseased parts adhering to the testes, and seeming to involve them, would not, in my mind, be a reason against the operation. The disease is so necessarily fatal if left to itself, that even in a doubtful case I should rather have recourse to the operation than leave untried what affords at least a chance of success.

A more important question in my opinion is, how far the operation may be advisable or justifiable when the glands of the groin become diseased? There is a paper in the twelfth volume of the *Medico-Chirurgical Transactions*, by Mr. Earle, on the subject of this affection; and he there says that the swelling of the glands of the groin will subside after the disease has been removed by operation; so that the mere existence of swelling in those glands is not to be deemed

a sufficient reason against its performance. I have seen this take place in the way that Mr. Earle has described—that is, I have seen the disease removed when the glands have been swelled, and the swelling of the glands has subsequently subsided. I should, however, make this distinction—if the glands are swelled without being indurated, I think the operation may be performed; but if the glands be hardened as well as swelled, I should then doubt the propriety of operating; of course if ulceration has taken place in the glands, I should regard that as a conclusive reason against the operation,

Subcutaneous Tubercle.

There is an affection which I ought to have mentioned to you when speaking of the diseases of the cellular system; it is the formation of a small tumor immediately under the skin, upon the cellular membrane, just under the cutis—a tumor which has been noticed incidentally by various writers, but which, I believe, has only been expressly treated of and described by Mr. Wood, of Edinburgh, who, in the Edinburgh Medical Journal for the year 1812, described this affection under the head of painful subcutaneous tubercle; and who, in the third volume of the Edinburgh Medical Transactions, which has lately been published, has described it more at large. It is a small hard tumor—so small, that in general it does not produce a conspicuous external appearance. It is seated immediately under the skin, is loosely connected to it and the surrounding parts, and over which the skin itself can generally be moved. The principal character of it is the severe pain which accompanies it, and from which Mr. Wood has called it the *painful subcutaneous tubercle*. This pain, however, is not a constant attendant on the swelling—it generally takes place in paroxysms, and these are so severe, that one would almost compare the pain to that felt by persons labouring under *tic-douloureux*. The patient complains frequently that the pain is of the most intolerable and insupportable kind: it will attack him in the night, awake him, and destroy his rest; and yet perhaps at other times he experiences no inconvenience. These small subcutaneous tubercles are the seat of similar attacks of pain when they are struck or hurt; at the same time, even for weeks, and even months together, the patient experiences no kind of inconvenience from them. They last for a great length of time without acquiring any great magnitude, seldom extending in size beyond a pea or a horse bean; and Mr. Wood mentions one case in which the disease had existed thirty years, the tumor being situated at the anterior part of the ankle, and it had then acquired only the size of a horse bean. When these tumors are examined, if you

make a section, the structure appears to approximate a good deal to cartilage, but is not quite so hard;—it is a kind of bony structure, of such firmness that it makes a kind of noise when you cut through it with a knife. It has been suspected that they are developed in, or connected with, the twigs of sub-cutaneous nerves; and the author of a recent anatomical work mentions expressly the same thing. Tubercles of this character are found occasionally connected with the twigs of nerves, and in some instances they may be actually developed in such; however, in the majority of instances, I do not know that this nervous origin has been traced, so that I cannot exactly say that this is a form of disease belonging to the nervous structure. There is only one mode of procedure with this affection—we must cut it out; the operation is safe, perfectly easy, and perfectly effectual.

Warts.

Warts consist of an enlargement of a portion of the texture of the skin, without inflammation, and accompanied with thickening and induration of the cuticular covering. I have already had occasion to speak of those warts that are formed on the external organs of generation of both sexes, in consequence of venereal sores; but what I am now alluding to is, warts that appear on other parts of the body, and which come without any obvious cause—on the hands particularly. They are often seen in young subjects; they exist in very considerable number, and they will disappear about the time of puberty, without any particular application or obvious cause. When they are so situated as not to produce any particular inconvenience, and not to occasion any deformity, they may be safely left to themselves. They sometimes, however, are so seated about the hands or fingers, as to interfere with some motion of the part, or some office to which those parts are applied; and they often occasion an unpleasant appearance, so that people are desirous of getting rid of them, and there is no great difficulty in accomplishing this.

Perhaps the simplest and the shortest way of proceeding is to cut off the thickened cuticle which covers the prominent part of the wart—shave it in successive layers till you come to the surface of the skin, and then you perhaps draw blood in two or three places. When you have thus denuded the surface of the skin itself, you then rub the part thoroughly with nitrate of silver, and one effective application of this kind will generally destroy the wart. If, however, it should not succeed, you cut off the part thus rubbed by the caustic, and renew the application again; or you apply acetic acid in the same way to the part. If you wish immediately to extirpate it, you can make

an incision on each side, cutting it off at the base. You may proceed to this mode if necessary, but I believe you will generally find lunar caustic quite sufficient to answer your purpose.

Corns.

Corns are affections of the skin, arising from inflammation of some portion of the cutis of the toes or the feet, in consequence of pressure from the covering upon those parts. This inflammation being attended with an unnatural secretion of cuticle on the part, a continuance of the irritation produces a continued growth of the cuticle, so that ultimately a firm, hard, horny substance is formed on the part in question, and this, by its pressure, increases the inflammation of the skin, and brings on a state of the part attended with very great inconvenience, and indeed a great deal of suffering to the patient. The skin originally is preternaturally sensitive, in consequence of irritation from the friction of the shoe; then on this preternaturally sensitive skin you get a hard or horny substance, which is pressed upon by the shoe or boot, and causes great inconvenience. In some individuals a great number of the toes on both feet—in fact, all the prominent parts, are affected by growths of this kind; and if these individuals persist in wearing shoes that are tight, they suffer a great deal of pain. This pain and inconvenience are felt more particularly at certain times of the year—those hot periods of the season when the feet naturally become heated in common with the other parts of the body, in consequence of the high temperature of the atmosphere.

The palliative cure of corns, as we may call it, consists in cutting away the indurated cuticle, so as to remove from the inflamed skin, at all events, this mechanical source of irritation. The feet are first soaked in warm water, so as to moisten the indurated cuticle; you then take a sharp knife and cut away the morbid cuticle which has accumulated over the inflamed parts of the skin. In doing this, after you have removed the inflamed part, you generally come to a sort of point, where the cuticle seems to extend deeper than at the other parts; indeed it appears as if at one point the disease extended farther into the skin than elsewhere, and this has been commonly called the *root* of the corn. It is said that you may lift up and take away in a mass that part of the hardened cuticle which is thus formed in the corn; but I apprehend it is not very easy to do this. However, if you cut away the thickened cuticle in this manner, and cover the part with soap plaster, or some other mild plaster, spread on leather, and direct the patient to wear shoes that produce no pressure, great relief is experienced. You find that usually the covering of the cuticle

re-forms after this operation; but if the patient avoids the external source of irritation, the corn will not become seriously troublesome. If, however, considerable inconvenience be still experienced, you may proceed to further measures for the more effectual relief of the case—that is, after shaving away all the thickened part of the cuticle—you may rub the skin with lunar caustic. Thus you diminish the inflamed and irritable state of the skin, and then perhaps have no re-formation of the corn, if you avoid the external exciting cause; at all events the patient will derive very great alleviation from this simple process.

Bunyon.

There is an affection somewhat allied to, and in fact often actually connected with corns, which, however, in some respects is different from them. It is that kind of swelling which is called *bunyon*. This forms on the prominent joint of the great toe, that is, the joint between the first metatarsal bone and the first bone of the toe, a part of the foot particularly prominent, and thus particularly liable to pressure from the boot or shoe. The swelling thus formed is larger, and generally attended with more redness of the skin and tumefaction, than we see in corn; but besides there is often a hardened and thickened state of the cuticle over the most prominent part of the swelling, which constitutes bunyon. I believe the swelling of bunyon itself consists of inflammation of a bursa mucosa, which is seated between the skin and the prominent part of the joint in question;—a bursa mucosa in a situation which is analogous to that of the patella or olecranon, and by the irritation of the bursa from the pressure of the boot or shoe, a state of inflammation arises with effusion into it. If you open this swelling, you find generally that a fluid escapes. When this is in a state of inflammation, you may adopt the same means that you would do in cases of inflammation of other bursæ—leeches, poultices, lotions, or cold applications. Now the prominent part of the skin is liable to become the seat of corn, and I believe in many instances the irritation thus produced is the cause of the inflammation of the bursa. Sometimes the inflammation of the bursa becomes so considerable that a formation of matter takes place—abscess occurs, and the matter makes its escape externally. If a corn form in this situation, you must adopt the means I have already described to you, and so far as the inflammation itself goes, you have only to adopt the usual antiphlogistic means, and afterwards take measures to protect the part which is the seat of disease from the pressure of the shoe or boot.

PHYSIOLOGY.

BY HARDWICKE SHUTE, M.D.

Physician to the Gloucester Infirmary.

[Continued from page 44.]

*On the non-existence of "Sensibility,"
so called, and on the identity of "Irritability" in all Structures.*

HAVING endeavoured to shew that the animal properties denominated irritability and sensibility are the same in origin; that muscular fibre and nervous matter derive their capacity of being excited to action by an appropriate stimulus from the same source, as far as the existence and continuance of these properties are connected with the respiratory changes of the blood; we have next to inquire how far the existence and continuance of these properties, as connected with the function of nervous matter, lead to the same conclusion.

Is it not distinctly admitted by physiologists that the nervous influence is a cause of both of these properties; that "the nervous fluids contributing to sensibility and irritability, are often disturbed in their regularity of action;" that "if we tie, divide, or merely compress a nerve of any kind, the muscle with which it communicates becomes almost immediately paralytic; but upon untieing or removing the compression, the muscle recovers its appropriate feeling and irritability;" that sensibility is a property of the nerves, and that "we cannot remove the nerves without destroying the irritable substance." If the irritability and sensibility of animal matter are equally suspended by the interruption, and equally restored by the supply of the nervous influence, it is clear that the phenomena connected with the dependance of these properties on the function of nervous matter, not only do not invalidate, but strongly corroborate the proposition, that muscular fibre and nervous matter derive their capacity of action from the same source. Are these properties the same in cause and effect?

We have hitherto spoken of sensibility as though it were simply the term by which physiologists express the capacity which nervous matter possesses of being excited into its appropriate action by its appropriate stimulus; and so

long as this interpretation is adhered to, we recognise in animal matter the property of sensibility. But there is, in our opinion, no animal property answering to the sensibility of modern physiologists—no property of living animal matter which corresponds with the modern definition of sensibility. "All the nervous functions," it is said, "are generally supposed to spring from one great property, which is denominated sensibility: by this word physiologists express—first, the power which the nervous system possesses of receiving and transmitting impressions, and producing corresponding changes in the sensorium." Now we have some difficulty in understanding what is here meant by the capacity of receiving an impression; but how an impression can be transmitted, we are wholly at a loss to conceive. An impression, according to its literal meaning, is a stamp, mark, or print, and implies the yielding of one body to the impulse of another; but how such stamp, mark, or print, can be transmitted, or what precise idea is intended to be conveyed by the expression, we are unable to determine. The effect of the impulse by which the impression is made—such, for example, as the vibration of the particles of the body to which the impulse is applied, may be transmitted; and the action of a nerve, resulting from the impulse of a material object, may, we conceive, be transmitted from one extremity of the nerve to the other; but this interpretation we are scarcely at liberty to adopt, since we are expressly told, that when an impression is made upon a nerve, "there is no motion or visible change, but the animal feels;" implying, as it would appear, that no motion takes place. Are we not speaking of a living nerve? Is it not the specific character of living matter to be excited to action (which necessarily implies motion) by the impulse of its appropriate stimulus? If it be contended that the impression upon the nerve does not, in ordinary cases of sensation, lead to a corresponding action in the nerve, it follows that the nerve is considered to be inanimate, and we are at once carried back to our original proposition, that there is no property of living animal matter which corresponds with the modern definition of sensibility.

If we look to the succeeding part of

the definition, namely, the power of a nerve to produce corresponding changes in the sensorium, we may perhaps arrive at something like a definite idea of what is meant by the transmission of an impression. When the appropriate power of the nerve is excited, an impression, it may be said, is made upon the extremity which constitutes the organ of sense, and immediately a similar impression is made upon that portion of the brain or spinal marrow which corresponds with the other extremity of the nerve; and as this change in the brain or spinal marrow takes place through the medium of the nerve, we express the fact by saying that the impression is transmitted. But the corresponding change in the brain or spinal marrow is, as we shall have occasion to shew, wholly imaginary; and if such be the case, it follows that the property of sensibility—that is to say, the power which nervous matter is considered to possess of transmitting an impression—rests upon no other evidence than the imagination of the physiologist. The phenomena of sensation, it will be said, justify the inference that this change does actually take place in that extremity of the nerve which constitutes the organ of sense, and through the medium of the nerve in the sensorium; and therefore justify the inference that nervous matter is endowed with the capacity of receiving and transmitting impressions, and of producing corresponding changes in the sensorium. Now it might easily be shewn that the phenomena of sensation, frequently termed perception, are wholly unconnected with the subject; inasmuch as we are expressly told that “it is no necessary part of this sensibility for these impressions to be perceived by the mind, or to become perceptions.” “It is,” says another physiologist, “essential to notice, that these two operations are not necessarily connected together; or, in other words, that it is no necessary part of this sensibility for the impressions to be perceived by the mind.” This point will, however, be more fully considered when we come to treat of the modification of this property, which has been denominated organic sensibility; and we shall, therefore, on the present occasion, confine ourselves to those facts which first suggested the existence of this property, and from which alone that part of the definition

which connects this property with the transmission of impressions, and the production of corresponding changes in the sensorium, has been inferred.

If we tie, divide, or compress a nerve selected for the experiment, an impression made upon the extremity of that nerve does not lead to sensation. Why? Because, says the physiologist, the transmission of the impression to the brain is interrupted. We do not of course suspend the capacity of receiving an impression in a mechanical sense, but if the expression be thus interpreted, sensibility is no longer the property of living animal matter, since every part of a living animal has, we are told, its peculiar function, to the performance of which it is excited by an appropriate stimulus. “The word function implies action, and action is, in all other instances, admitted to be the result of an impression.” “Its susceptibility of the impression of such stimulus is denominated its irritability.” Are we not distinctly told, that “every operation of the vital energy is called an action?” But it is equally a physiological axiom, that “the vital functions depend on the organization of the parts in which they reside. A power which can exist independently of the peculiar organization of the part in which it resides, is not a vital power.” Action, therefore, is the necessary consequence of an impression made upon a nerve whose organization is perfect; but does it, therefore, follow that action will take place in a nerve, the integrity of whose organization has been destroyed? If the integrity of the animal organization be necessary to the existence of a living action, it follows as a necessary inference that no living action can take place when the organization is imperfect. Now it cannot be contended that the organization of a living nerve is unimpaired by its compression or division; and therefore it cannot be contended that, when sensation is interrupted by dividing, tying, or otherwise compressing a nerve, an impression upon the extremity of that nerve does not lead to sensation, because the transmission of the impression, that is to say of the living action resulting from the impression, is interrupted. We have not only no evidence that a living action takes place in the extremity of the nerve under these circumstances, but cannot even presume the existence of such action, because such presump-

tion is in direct contradiction to the physiological axiom, that "the vital functions depend on the organization of the parts in which they reside. Can a healthy action be supposed to take place in the extremity of a diseased nerve? If there is no action, or if no healthy action takes place, it is clear that the change in the state of the nerve, which, under ordinary circumstances, leads to sensation, does not occur; and it is, therefore, a false inference that sensation does not take place when a nerve is divided, because the transmission of that change which, under other circumstances lead to sensation, is interrupted. It is proved by the experiment that communication between the extremity of the nerve and the brain is essential to perception, but the acknowledged necessity of such communication still leaves the question undetermined, whether the action of the extremity of the nerve be dependant on the brain, or the supposed action of the brain on its communication with the extremity of the nerve. Physiologists, it may be said, are at liberty to adopt either explanation, but this we deny, because the dependance of the action of the extremity of the nerve on the brain is satisfactorily and unquestionably proved by all those circumstances which connect the action of muscular fibre with the brain through the medium of an appropriate nerve; whilst the dependance of the action of the brain on the extremity of the nerve is not only unsupported by experiment or observation, but involves the physiological contradiction of attributing different functions to the same structure. Is it rational to adopt such an explanation in preference to that which reconciles the phenomena in question with the acknowledged and uniform operation of nervous matter?

If a nerve be divided, an impression made upon that extremity of the nerve which still communicates with the brain will, it is said, lead to sensation. Now it is not quite clear that, under the circumstances mentioned, the impression is not made upon the extremity of another nerve, of a nerve which terminates naturally at the point where the impression is made, and which is, therefore, perfect in its structure. "Changes produced on the coats of the nerves, cannot," says Dr. Monro, "miss to affect the nervous febriles." The cellular substance may be too full of liquor, or may

not supply enough; the liquor may not be of due consistence, or it may be preternaturally obstructed and collected. The pia, or dura mater, may be too tense or too lax; their vessels may be obstructed; their proper nerves may be irritated, or lose their power of acting." Admitting, however, that the nerve which has been divided is the identical nerve in which, under the circumstances mentioned, the sensation originates, the fact only proves that communication with the brain is essential to perception; still leaving the question undetermined, whether the sensation takes place in consequence of the brain supporting the action of the extremity of the nerve, or of the action of the extremity of the nerve leading to a corresponding change in the sensorium. We are of opinion, therefore, that there is no satisfactory evidence of any nerve being endowed with the capacity of transmitting an impression, and have next to inquire how far the power which a nerve is said to possess of producing corresponding changes in the sensorium, has been legitimately inferred from the phenomena of sensation.

"The proof of the existence of a common sensorium depends," says Dr. Bostock, "upon the facts which have been referred to above, where impressions made on an organ of sense are not followed by a perception, provided the nervous communication between the organ and the brain be destroyed or injured." Now this fact, as we have endeavoured to shew, only justifies the inference, that a communication between the extremity of the nerve and the brain, we might say between the brain and the extremity of the nerve, is essential to sensation; but the explanation of the fact is equally intelligible, whether we attribute the loss of sensation to the absence of that change in the extremity of the nerve which constitutes the first link in the animal process of sensation, or to the want of that change in the sensorium which is imagined to be the result of an impression made upon an organ of sense, and to be more immediately connected with the operation of the mind. Now we adopt the former opinion, because it involves no peculiar views of living action, the change in the state of the nerve being the natural and ordinary result of an impression made upon living animal matter, because it does not call upon us to

imagine that an injured nerve retains its power of action unimpaired; because it does not require for its support the irrational hypothesis that the same structure, the same as far as such structure is cognizable by our senses, is endowed with properties so different, as that of conveying a material substance from the brain to the extremity of a nerve, and of transmitting an impression from the extremity of a nerve to the brain; because it does not call upon us to sacrifice that which we know, and which cannot rationally be denied, to that which we do not know, and rests upon no other evidence than the prolific imagination of the physiologist.

"The same conclusion," continues the author before mentioned, "seems to be confirmed by a series of facts the reverse of these; where, when an effect has been produced on the brain, similar as we may suppose to one which had on some former occasion been transmitted to it from an organ of sense, it has excited the idea of an external impression, although the organ of sense may have been destroyed. This is the case with persons who, after having arrived at maturity, have had the eyes entirely destroyed; yet such persons continue to dream of visible objects, and are able to recal visible ideas with perfect facility!!" This is, indeed, a singular argument. The supposition of a change taking place in the sensorium in ordinary cases of sensation is confirmed, not by the fact, but by the supposition, that an idea arises from a similar change in the sensorium, which supposition rests upon no other evidence than the original supposition, that a change does take place in the sensorium in ordinary cases of sensation. The fact simply proves that an idea is not dependent on a change in the organ of sense, and thus distinctly proves that an idea and a sensation are not physiologically the same, a change in the organ of sense being under all circumstances essential to the existence of a sensation. An idea, it may be said, is nothing more than a recalled sensation,—is, in fact, the original sensation not at all altered by the circumstance of its being recalled, and, therefore, the original and the recalled sensation must be supposed to be dependent on the same cause. This cause, in the example of a recalled sensation when the organ of sense has been destroyed, is obviously not dependent on

a change in the organ of sense, and it therefore follows that the original sensation must have been dependent on some other cause than the change mentioned. Now if it can be shewn that an idea is not a recalled sensation—that an idea is distinguished from a sensation by the very circumstance of its not being dependent on a corresponding change in nervous matter, it will follow that physiologists reason upon false premises when their argument is founded upon the assumed fact, that an idea is referrible to "an effect produced on the brain similar to one which had on some former occasion been transmitted to it from an organ of sense." If two individuals look at a distant object, the impression upon the retina of each must, *cæteris paribus*, be the same, and yet the idea is not always the same, because the object is pronounced by the one to be a horse, and by the other a tree. How can an idea be the representative of a change in the organ of sense, or of a corresponding change in the sensorium, if two individuals have different ideas of an object, which causes the same change in the retina and in the sensorium of each? An impression upon an organ of sense leads, we are told, to a corresponding change in the sensorium, and if such be the fact, it is obvious that, in the example mentioned, the idea is not in both instances correspondent with the change which actually takes place in the sensorium. But an idea differs from a sensation in its capacity of representing that which is immaterial, and therefore incapable of making an impression on nervous matter. For example:—"To judge," says Magendie, "is to establish a relation between two ideas, or between two groups of ideas. When I judge of the goodness of a work, I feel that the idea of goodness belongs to the book." Now the goodness, the quality of a book, cannot possibly make an impression on nervous matter, and yet it is here distinctly admitted that such quality gives rise to a corresponding idea. There are certain external characters of the human body which suggest the idea of a person having lived a certain number of days, months, or years; we connect with these characters the idea of a certain period of time having elapsed since the birth of the individual, and this period of time we denominate age. Now the lapse of

time cannot possibly be supposed to lead to a corresponding change in nervous matter, and yet we have a distinct idea of the lapse of time. We are conscious of our own existence, that is to say, have a distinct idea of the fact that we exist, and yet the fact of our existence cannot be supposed to produce a corresponding change in nervous matter. We have a distinct idea of an Almighty Power which rules the universe, but how such power can produce a corresponding change in nervous matter, we have still to learn. We have thus, in the examples mentioned, a distinct idea of that which is incapable of making a corresponding impression on nervous matter, whilst the definition of a sensation necessarily and always implies a change in nervous matter resulting from the impression of a material object. The argument which rests upon the assumed identity of a sensation and an idea is, therefore, physiologically incorrect, inasmuch as the former is the immediate effect of an impression on nervous matter resulting from the impulse of a material object, whilst the latter is often, if not always, the representative of that which is immaterial, and therefore incapable of making an impression on nervous matter. The fact of the sensation of a visible object being connected with a change in the organ of vision is, therefore, no argument in favour of the supposition, that the idea of such object is connected with a change in the sensorium; and if there be no reason to suppose that the idea of a visible object is connected with a corresponding change in the sensorium, the fact of such idea occurring independently of a change in the organ of sense, is no argument in favour of the supposition, that the sensation of a visible object is connected with a corresponding change in the sensorium.

"It is," continues the same author, "partly also upon the principle of the actions of the brain producing effects similar to those that follow from impressions upon the extremities of the nerves, that we account for the mistaken perceptions that are experienced after the loss of a limb, which are frequently not to be distinguished from those that formerly existed in the part." The argument is obviously founded on the assumed identity, as far as the brain is concerned, of the original sensation and the subsequent idea, but with this

important and additional fact, that the idea is obviously the representative of a similarity between the original and the present sensation, and is thus the representative of that, which is incapable of making an impression on nervous matter.

We are not aware of any other argument which has been advanced in support of the existence of a sensorium commune, except that which arises from the suspended or impaired sensation which often results from diseases or injuries of the brain. "It is, therefore," says Baron Haller, "a false position that the mind perceives immediately in the nervous branches or sensible organs themselves; for this opinion is confuted by the pains which a person will feel in a limb after it has been cut off, and from the interruption or removal of all pain by a compressure of the conveying nerve, with the disorders of the senses from different affections of the brain." Now it cannot be denied that the action of the mind—that is to say, the exercise of the perceptive powers—is dependant on the functions of the brain; and it is therefore obvious that, consistently with our former observations, the loss of sensation in apoplexy, epilepsy, syncope, and injuries of the brain, is not necessarily referrible to the fact of no corresponding change taking place in the sensorium, since the loss of sensation under these circumstances is as obviously referrible to the facts of the impressions on the organ of sense not leading to the necessary change in that organ, in consequence of the dependence of that organ on the brain; or of the perceptive powers, in consequence of their dependence on the brain, not being in a state to perceive the change, supposing it to take place.

It has been ascertained, by an accurate examination of the spinal nerves, that they consist of distinct filaments, arising from the anterior and posterior portions of the spinal marrow; and by tracing these filaments from their different origins to their different destinations, it has been found that the anterior filaments are nerves of motion—that is to say, terminate in the muscular fibre—whilst the posterior filaments may be traced into "the skin of the neck, trunk, and members;" and have been denominated nerves of sensation. We shall endeavour, in a future part of

these observations, to shew that the phenomena of motion and of sensation, as connected with the different nerves, are not irreconcilable with the proposition that the function of these nerves is the same; the difference of effect being referrible, not to the nerves, but to the organs and perceptive powers with which they are connected. It is sufficient for our present purpose to say, that when the changes in the state of the skin, or of the nerves supplying the skin, are observed by the animal, and become perceptions, it does not follow, from the circumstance of these nerves originating in, or being connected with, the posterior portion of the spinal marrow, that these actions are observed and become perceptions because they are transmitted to the sensorium. If the retrograde action of these nerves cannot be legitimately inferred from the phenomena of sensation (and we have given our reasons for entertaining that opinion), there is nothing in the fact of these nerves being connected with the posterior portion of the spinal marrow from which such retrograde action can be inferred. We are, indeed, disposed to believe that their origin in the posterior portion of the spinal marrow is referrible to the simple circumstance of such origin being the most convenient for their distribution; inasmuch as they are thus enabled to arrive at their destination—namely, the exterior part of the body—without crossing or interfering with those nervous fibrils which originate in the anterior portion of the spinal marrow, and are distributed to the more internal parts of the body—namely, the muscles. It has also been ascertained that an animal does not express pain when the portio dura of the seventh nerve (a nerve of motion) is pinched, torn, or otherwise injured; whilst considerable pain is apparently felt when the portio mollis of that nerve, or “the upper branch of the fifth pair, which gives sensibility to the skin or mucous membranes of all the anterior part of the head,” are subjected to similar causes of irritation. But the fact of the animal perceiving the change in the state of particular nerves only, does not justify the inference that the one change is perceived because it does, and the other unperceived because it does not, produce a corresponding change in the sensorium. The facts of these nerves being different in their origins and desti-

nations, or of the actions of one of these classes of nerves only being perceived by the animal, do not in any way impugn the propositions—that there is no animal property corresponding with the modern definition of sensibility, and that the irritability of animal matter is in all structures the same.

REMARKS

UPON

BOTANY AND INSTITUTIONS OF MEDICINE,

As constituting a Part of Medical Education.

BY WILLIAM HOWISON, M.D.

Lecturer on Materia Medica, Botany, &c.

AN individual unconnected with the medical profession (but much more so a medical man), upon carefully perusing our Edinburgh Medical and Surgical Regulations for the education of young men, will naturally ask—Is a knowledge of botany essential to the practitioner? If it be, and no sensible man will give him any other answer, the University of Edinburgh (and every other University) in their Statuta Solemnia, do right in making it form an essential part of the education for acquiring the degree of Doctor of Medicine. The next question which will naturally occur is, why do the College of Surgeons and Apothecaries of the same celebrated school of medicine (the only acknowledged body of apothecaries in Edinburgh) omit such an important branch from the regulations for their diploma, or liberty to practise? Does a physician, the prescriber, require a knowledge of botany; and is a similar knowledge unnecessary to the apothecary, who makes up his prescription? Are they of opinion that a proper knowledge of materia medica can be acquired by an individual completely ignorant of botany? The answer of these questions I leave to the majority of that learned body. They prefer the elements of mathematics and mechanical philosophy to botany, or medical jurisprudence. The education, however, of the Edinburgh College of Surgeons will not be complete until botany is added to the course of their study.

The Apothecaries' Company of London, in their last regulations, have omitted the word *medical* (their former regulations including one course of *materia medica* and *medical botany*), and have now included two courses of *materia medica* and *botany*. Would it not have been more proper and scientific for them to have separated *botany* from *materia medica* entirely; and to have said, one course of *materia medica* and one course of *botany* (the same in reality, so far as regards time and expense to the student)? Are they averse to follow, or have they not seen, the example of Sir James McGrigor, in the excellent regulations of the Army Medical Board, for so many years looking them in the face? Would the Navy Medical Board not do well in adding a three months' course of *botany* in their regulations?

Botany and *materia medica* ought to be separate and distinct courses. They can never be properly taught together. *Botany* cannot be taught with propriety during the winter season, which is the time at which the greatest justice can be done to *materia medica*. Why do the London regulations not combine pharmacy with *materia medica*, in place of *botany*; as is done in Scotland? Are the two not most intimately allied together? Why do they not even mention pharmacy? Is it not of as much consequence to the physician, surgeon, and apothecary, as *materia medica*? Does not the London Pharmacopœia consist one half of pharmacy and one half of *materia medica*?

Combining *materia medica* and *botany* in one course, as is at present done in the regulations of the Royal College of Surgeons and Apothecaries' Company of London, and which teachers are compelled to act up to, to make their tickets qualify, is most improper. The *botany* is superficially taught, if taught at all; and men are forced to come forward—viz. teachers of *materia medica*,—to make it known to others who have never given it their practical attention, and who are ignorant of it themselves. *Botany* is not the superficial study which men ignorant of its minutiae are apt to suppose. It is only to be acquired by industry, labour, the toil of summers in the fields, aided by a natural genius or attachment for its study. If Linnæus, Sir James Smith (men whose lives were totally oc-

cupied in its pursuit), and many other individuals now existing, were to be asked how *botany* ought to be taught? their answer would never have been in conjunction with *materia medica*, or by individuals forced into its service. By the periodical journals of the day, I am happy to see that Botanical Gardens and Societies are now set a going in London, by Mr. Frost and others; and certainly the public, and medical profession in particular, are called upon to encourage such labours. It may be unnecessary for me to add, that *botany* ought to be taught to medical students by medical practitioners in active practice, and by no other individuals.

It is a mistaken idea, although a very prevalent one, that general *botany* can no where be properly taught without a botanic garden. Such may be the case in London, or in over-grown cities. In Edinburgh it can be taught with perfect advantage, independent of such a garden. Arthur's Seat, and Salisbury Crags, close to the town, abound in a constant and ever varying supply of plants. Blackford, Braid, and the Pentland Hills, with alpine plants; Duddingstone and Lochend with water plants; the coasts of the Firth of Forth with marine plants; and the surrounding level country with those of the plains;—all wild, in the state of nature, unaffected by cultivation, as those in botanic gardens are, and in the only suitable state for teaching *botany*. Even our University Professor throws aside to a considerable extent the superb Botanic Garden at his command, and avails himself of the above-mentioned resources, employing his gardeners during most of the summer in collecting the plants then growing. Excursions in such a neighbourhood afford an entertaining, healthful, and an advantageous addition to a course of botanical lectures.

Every medical man ought to know general *botany*, as an interesting and beneficial part of his profession, and he can only acquire that knowledge by attending diligently and attentively one or more courses of *botany* of three months' duration. Every medical officer entering the army, navy, or East India service, where he possesses ample opportunities of moving from place to place over the earth's surface, ought to know intimately *botany*, as putting it in his power to benefit the human race, and

to employ his spare hours to advantage. The carrying this improvement into effect, lies with the different medical bodies, the Army, Navy, and India Medical Boards, to insist upon every student attending a course of botany, with botanical excursions of at least three months' duration, previous to getting his diploma, or being allowed to enter the public service of his country.

Institutions or Theory of Medicine.

Institutions of medicine have from time immemorial been a distinct and separate class in the Edinburgh, Glasgow, and Dublin Universities, and with propriety. The only error the new London University has committed is in substituting an imperfect course of physiology, consisting of only three lectures a week for three months, for the more perfect one of institutions of medicine, consisting of five lectures a week for five months.

The Royal College of Surgeons of Edinburgh, in their last Regulations, have improperly termed this class institutions of medicine or physiology, in place of theory of medicine; whereas it consists of five lectures weekly for above five months, and must embrace physiology, therapeutics, and even pathology, history of medicine, &c. to fill up so much time.

Is there any course on the institutions of medicine given in London? The Navy Medical Board require their candidates to attend twelve months theory and twelve months practice of medicine. Do they mean that the candidate shall attend two six-months courses of theory or institutions of medicine, and two six-months courses of practice of medicine, which can only be got in Edinburgh, and which is most proper; or, that he should attend twenty-four months of theory and practice embraced together as taught in London? *viz.* eight distinct courses of three months' duration? Monstrous! Or will either of these answer the purpose? If any individual employed in the teaching of medicine will think it worth his time to answer one or all of the queries contained in the preceding paragraphs, he will oblige their author.

Application of Flour to Leech-bites.

As a postscript to the foregoing paper, allow me to recommend to the

medical profession a thick layer of wheat flour dusted upon flannel, as a rapid and efficacious means of stopping the hæmorrhage from leech bites. I now use this on every occasion, and have found it far superior to powdered loaf sugar, nitrate of silver, caddis, or any other means which I have heard proposed. It is particularly cleanly, preventing the clothes of the individual from being drenched with blood during the night, or when in bed.

Application to the Face in Tooth-ache.

Also a thick flannel compress wrung out of the following solution heated to near the boiling temperature, and kept applied for half an hour morning and evening, to the affected part, as a most excellent discutient in inflammation and suppuration of the face, in consequence of carious teeth, a complaint which has been very common in Edinburgh this winter, aggravated by the severity of the winter. I lately suffered most severely from this complaint, and found the above remedy the only one which gave effectual relief, after friction with camphorated oil, warm water fomentations, camomile poultices, friction with dry flannel, &c. had been tried in vain. The power of the muriate of ammonia solution in increasing the action of the absorbent vessels, and thus carrying off the swelling, was surprising.

ANALYSES & NOTICES OF BOOKS.

“ L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

On the Motions and Sounds of the Heart. By D. J. CORRIGAN, M.D.
From the new Volume of the Transactions of the Association of Fellows and Licentiates of the King and Queen's College of Physicians in Ireland. Dublin, 1830.

FEW facts in physiology have been apparently better ascertained than the cause and circumstances of the heart's impulse. By the heart's impulse we

understand its peculiar pulse—its beating against the side of the chest—"the apex striking against the left side, opposite the interval between the sixth and seventh true ribs"—as the text books say. It has been generally, nay almost universally, attributed to the contraction of the ventricles; but this alone, says John Hunter, "could not produce such an effect; nor could it have been produced if it had thrown the blood into a straight tube in the direction of the axis of the left ventricle, as is the case with the ventricles of fish, and some other classes of animals, but by its throwing the blood into a curved tube, viz. the aorta. That artery, at its curve, endeavours to throw itself into a straight line, to increase its capacity; but the aorta being the fixed point against the back, and the heart in some degree loose and pendulous, the influence of its own action is thrown upon itself, and it is tilted forward against the inside of the chest." And so, upon the indisputable authority of this eminent man, the matter was supposed to be completely set at rest.

But careful observation, and repeated and well-attested experiments, have induced the author of the paper under review to dissent from the generally-received opinion; he has ventured, and we think very rationally, to dispute the sanction of great names, and to propose a solution of the moot point at once plausible, satisfactory, and ingenious.

If we take into consideration the true course of the aorta (for the best description of which the reader is referred to Portal's *Cours d'Anatomic Medicale*, tom. iii. p. 141), and suppose the arch to make an attempt at straightening itself by tilting up its loose extremity, this extremity must move, not towards the left side, but away from it, and towards the right. The heart being attached to the loose extremity, it necessarily follows that, if the arch could straighten itself, and take the heart with it, the heart would be carried by such straightening in the same direction,—that is, away from the left side. The direction of the pulmonary artery is parallel, or nearly so; and its tendency, therefore, in case of straightening, is to assist the aorta in propelling the heart towards the right side. Hunter's explanation would consequently seem to be at variance with the anatomy of the

heart and its large vessels. This, however, is not the only objection that may be urged against the cause of the heart's impulse assigned by Hunter. Both he and Dr. Bostock have fallen into a mistake with regard to the abstract physical fact of the motion produced by the injection of the aorta. This artery being always full in the living body, the reaction that takes place must be in the direction of the axis of the orifice of the aorta, no matter how the artery afterwards curves. "But," says Dr. Bostock (*Physiology*, vol. iii. p. 398), "I conceive that, if a curved elastic tube that is fixed at one end and hanging loose at the other, be suddenly injected, the injection will tend to elevate the loose end, whatever may be the direction of the curve with respect to its orifice." Our author replies: "In the first place, there is no analogy whatever between a curved tube with an open end, and the aorta; secondly, in such an experiment as that which Dr. Bostock describes, the loose end will be moved, not by the impulse of the fluid injected through the tube, or by its reaction on the curve, but by the reaction generated at the orifice when the fluid quits the tube. The direction of the discharging surface, with regard to the curve, instead of being immaterial to the effect produced on the curve, as Dr. B. asserts, is, in fact, the regulating influence, that determines which way the loose extremity of the tube shall move, and what shall be the effect produced upon the curve, whether increased or diminished.

"I shall here, as on every occasion when it is possible, instead of referring to abstract laws from physics, have recourse to direct and simple experiment. To demonstrate the fallacy of the assertion made by Bostock, Magendie, Hunter, Senac, and indeed by all physiologists who have supported their opinion, take the ordinary stomach-pump, with a long curved elastic tube attached; inject water forcibly through it, and you will find, that when the orifice is curved in towards the pump, the extremity of the tube will move outwards, or the tube will tend to straighten itself. If the orifice be pointed outwards, or away from the pump, the loose end will move inwards, or the curve will be increased. When the orifice is turned to the right or the left side, the tube will move in the opposite di-

rection. These movements of the tube prove to demonstration that the straightening of the curve, when it does take place, instead of being independent of, is altogether governed by, the direction of the discharging orifice. The accompanying diagram will explain my meaning better than words. Fig. 1, A,

Fig. 1.

Fig. 2.

represents the tube with its orifice turned inwards. B, the position which the tube assumes from the reaction generated at the discharging orifice. Fig. 2. represents the experiment reversed: A, the tube with its extremity or discharging orifice turned outwards. B, the same tube driven in, or the curve increased by the reaction of the fluid rushing out. The principle embraced by Hunter, that a bent tube like the aorta will be straightened by the action of the fluid impelled through it, and the illustration offered by Dr. Bostock in support of this principle, are therefore both erroneous;—their application, of course, must be equally so."

Another, an *ad absurdum*, and indeed a strong argument against Hunter's explanation, is, that if it were true, the impulse against the side should not be felt until *after* the arterial pulse; for the arteries being always full, and fluids being almost incompressible, the pulse must be felt in the arterial branches the moment the ventricle begins its contraction; while the heart should not strike the side until a moment after the pulse is felt, when the ventricle has driven its contained blood into the aorta and has dilated its arch. But will any one venture to assert that the impulse against the side is felt *after* the impulse at the wrist?

There is another explanation of the heart's impulse offered by some eminent writers, who attribute it to the dilatation of the left auricle. But the slow filling of the auricle never could produce the rapid impulse with which the

heart strikes the side. Senac, with whom the idea originated, saw the difficulty, and very properly placed little or no confidence in it. Neither is Mr. Alderson's explanation more tenable; his hypothesis is ingenious, but he displays in it a more intimate knowledge of physics than of anatomy and physiology.

Having shewn that all the causes hitherto assigned for the heart's impulse "would either produce an effect diametrically opposite or are totally insufficient to accomplish it," our author proceeds to assign a cause adequate to the explanation of the phenomenon. This we may at once lay before the reader. The impulse of the heart against the side, then, according to Dr. Corrigan, is produced by the filling of the ventricles—or, as it may be more proper to state, the active agent in the operation, the heart's impulse, is owing to the *contraction of the auricles*.

This is an important, and, as far as we know, an original announcement. We shall, therefore, take ample note of the proofs; and we have need to do so calmly and dispassionately, for they begin by questioning a position hitherto almost taken for an axiom. Is it true that it is during the systole of the ventricles that the heart strikes the side? Dr. C. asserts that is not. Let us see, then, how he supports his assertion. It is, we find, a matter of simple experiment. Place the index finger of your right hand on the spot where your heart beats most strongly, whilst you put your left thumb on your right radial artery. When the heart beats slowly and forcibly, you perceive distinctly that the first tap is against the ribs, the second from the pulse; and the latter incontrovertibly denotes the contraction of the ventricle. How, then, can the heart's impulse arise from the contraction of the ventricle? The fact is, that here has been an assumption and a fallacy of long standing—an error taken upon trust, sanctioned by eminent names, and reiterated from one physiological writer to another; so that what was at first but bare assertion, through the credulity and indolence of successive observers was received, at length, as an undisputed truth—a veritable axiom. Now any one may confute it, and convince himself that the impulse of the heart against the side is anterior to the impulse in the arteries.

Besides, the actual inspection of the heart, in experiments made on living animals, plainly corroborates the statement. The impulse of the heart against the side does not take place, as it appears, until the heart has been almost fully dilated—of course, until the auricle has nearly *finished* its contraction. The impulse in the arteries, on the contrary, from their being always full, is felt at the very instant the ventricle *begins* to contract; and the interval is often so instantaneous as to be scarcely perceptible. Hence we may easily conceive how the mistake originated.

The following notes of the experiments just now alluded to, are too important to be omitted. "Our first object was to examine the heart in the living animal. A rabbit was selected, and, before proceeding with the experiment, the stethoscope was applied. Both sounds of the heart (the long and short sounds, of which more anon) could be distinctly heard. The right side of the chest was opened, the mediastinum being left uninjured. Respiration went freely on, little blood was lost, and we obtained a view of the heart in action far superior to any thing we could have anticipated. The animal lived in this state for about twenty minutes; sufficient time for accurate examination. Immediately after the operation, and when the heart was first brought into view, its motions were very rapid and tumultuous; but in a few moments they became less frequent and more regular, and the movements of the different parts plainly distinguishable: first the contraction of the auricles; second, the contraction of the ventricles; then the pause. At each contraction of the auricles the heart came forward, the ventricles being dilated in every direction, and driven downwards and forwards; at each contraction of the ventricles the heart retired into the chest. The contractions of auricles and ventricles were quick, but it is impossible to describe the rapidity with which the contraction of the ventricle followed that of the auricle. When the heart was beating violently, the succession was so rapid that the eye could scarcely distinguish between the two contractions.

"To ensure accuracy in our observations, a red vessel, or some line beyond the heart's apex, was chosen for the eye to rest on, and the motion of

the organ, towards and from it, was marked. Each time that the auricle contracted, the heart came forward; each time that the ventricle contracted, the organ retired.

"Authors describe the point of the heart as being tilted up, struck against the ribs; we could observe no such motion. The heart first applied itself to the parietes of the chest, by a small surface almost midway between the base and the apex, which quickly increased in extent.

"The stethoscope was now placed on the left side of the sternum, and while one of us listened to the sounds of the heart's action, and tapped with his finger at each impulse and dull sound, the others marked by the sight the visible contractions of the heart. The tap indicating the impulse and dull sound came after each pause, and synchronous with the contractions of the auricle, the ventricles being at the same instant dilated and propelled forward, the appendices of the auricles at the same time retiring. Another now took the stethoscope; the experiment was conducted in the same way, and with a similar result. These experiments were repeated six times on rabbits, and again, on a larger animal, and invariably with the same results.

"In warm-blooded animals, the motions of the heart are rapid, but particularly under pain; and hence it was difficult, even for the eye, when the chest was first opened, to follow its movements. The heart of a reptile, on account of its slow movements, and the little comparative sensibility of the animal, is free from this inconvenience. The heart of a frog, even under operation, beats only between fifty and sixty in the minute, so that the movement of each part can be most distinctly seen.

"Dr. Bostock describing the motion of the heart in a cold-blooded animal, uses the following words:—'For a short space of time the heart lies at rest, and suffers itself to be distended with blood; then it is suddenly seen to rise up on its basis, to shorten its fibres, and to expel its contents.' We may observe, first, that there is in this description a contradiction both to his own assertions in another part of his work, and a refutation of his theory of the heart's impulse. Dr. Bostock makes in this description the rising up of the heart anterior to the contraction of the ventricles. He says

in another place, 'I may without impropriety assert, that the beating is felt *not* at the instant when the ventricle *begins to contract*, but when the contraction has produced its effect on filling the arch of the aorta.' In the first quotation, according to Dr. B. the heart *first* rises up, that is, beats, *then* expels its contents; in the second passage, the heart *first* fills the arch of the aorta, that is, expels its contents, and then beats. He asserts with Senac and Hunter, that the filling of the arch of the aorta by the contraction of the ventricle, is the cause of the heart's rising and giving the impulse; yet in the description just quoted, he makes the rising of the heart anterior to the filling of the arch. Dr. Bostock's description is, however, not only at variance with his own assertions and theory, but it is even quite erroneous in point of fact. This the inspection of the heart in the living frog clearly shewed. Having removed the inferior portion of the sternum, and thus brought the heart clearly into view, the following phenomena were observed. The heart did not suffer itself to be distended with blood, as Dr. Bostock states; the blood was thrown into it by the auricle contracting with great energy. It did not rise up on its basis, but was dilated and driven downwards and forwards by the blood expelled from the auricle, and finally, as the ventricle contracted, the heart retired from the surface, being deepest in the chest, at the moment when the contraction was at its utmost.

"The heart of a frog is very large compared with the size of the animal; its movements are very slow, and its parietes, although strong, are almost transparent. These circumstances, but above all, the transparency of the walls of the organ, give the greatest certainty to observations on the actions of the heart in this animal, the presence or absence of blood in the ventricle being marked not alone by the increase or decrease of size, but also in the most beautiful manner, by the change of colour. The heart is quite pale when the ventricle is contracted or empty; a deep rich purple, when it is dilated or full of blood. This change of colour was an additional test of the accuracy of our observations, which we did not possess in warm-blooded animals. When the auricle was distended, it came fully into view; when it contracted, it did so

with great energy, retiring quickly from our sight. At the same instant the ventricle swelling, being distended with blood (as shown by its sudden change from extreme paleness to a rich purple colour,) was impelled with some force against the finger, the contraction of the ventricle following quickly upon its dilatation. It diminished itself in every direction, bringing its sides together, and its apex towards the base, and as it contracted, retired until its perfect paleness proved that it had expelled all its blood; the heart at the moment when its contraction was at its height, being deepest in the chest. Repetitions of this experiment confirmed our observations in every particular.

"We consider the examination of the heart of the frog as quite conclusive. Could a shadow of doubt have remained on our minds after the examination of the warm-blooded animals, it would have been completely removed by the inspection of the heart of this reptile; the change of colour presenting an infallible test of dilatation and contraction.

"Having now gone through the detail of the experiments on the living heart, we present the facts ascertained:

1. The auricles contract first.
2. The ventricles second.
3. Then the pause, or state of rest.
4. The contraction of the ventricles is rapid, and follows quick as can be conceived after that of the auricles.
5. The contraction of the auricles is comparatively slow.
6. The heart strikes the side when the auricles contract.
7. The heart retires when the ventricles contract.
8. The beat of the heart is produced not by the tilting up of the apex, but by its swelling and coming against the ribs, in consequence of the impulse given by the rush of blood from the auricle."

We regret that our limits at present will not permit us to notice Dr. Corrigan's very interesting observations on the sounds of the heart; but we hope to have an opportunity of doing so in an early subsequent number.

COATS OF THE TESTICLE.

To the Editor of the London Medical Gazette.

SIR,

In your review of Sir Astley Cooper's recent work "On the Structure and Diseases of the Testicle," you remark that, different from the nomenclature of Haller, Hunter, Pott, Warner, Sharpe, Earle, Ramsden, &c. "Sir Astley Cooper terms the first coat (*i. e.* the tunica vaginalis) *tunica vaginalis reflexa*; and the second coat (*i. e.* the tunica albuginea) *tunica vaginalis testis*; while he applies the term *tunica albuginea* to what may be considered a newly-described coat—one which lies under the last, and embraces closely the glandular texture of the testis." "To say, therefore," it is further added, "that the tunica albuginea of our best authors is *tunica vaginalis*, is just that sort of inaccuracy which is apt to puzzle the student."

Without meaning to invalidate the correctness of your remarks in general, I may be permitted to observe that the present nomenclature is the same as Sir Astley Cooper always used to employ in his anatomical description of this part of the body, while I was attending his lectures as a student; and I have now before me a diagram in illustration of this very point, from Sir A. Cooper's own words, distinctly shewing a *tunica vaginalis reflexa*, a *tunica vaginalis testis*, and the proper investing membrane of the testicle itself, a *tunica albuginea*; which last tissue or fibrous texture contributes to form the several compartments, or septulæ, containing the bloodvessels and the innumerable coils of the seminiferous tubes. Moreover, referring to Mr. Green's concise and accurate Dissector's Manual, it is there remarked that the "*tunica albuginea* is the *proper* covering of the testicle," and that "it has been *confounded* with the *tunica vaginalis*, but differs from that membrane in structure;" so that the *tunica albuginea* need not be "considered as a newly-described coat," as is observed in your Gazette. (See Green's Dissector's Manual, sect. ii. part ii. 1820.) It is likewise stated by the same confidential authority, that "the *tunica vaginalis* gives a *double* covering to the testicles,—it is first a

close covering, and is then *reflected*, so as to give it a second or loose covering;" and that the "whitish colour" of the close portion arises from the *tunica albuginea* "shining through the *tunica vaginalis*." In an interleaved copy of the Dissector's Manual in my possession, there is annexed to the pages treating on this subject another diagram, exactly illustrative of what has been just described.

Perhaps you will insert these observations in support of a nomenclature which, although it may be strange to some, must be familiar to the anatomical students of the school of St. Thomas's Hospital; and allow me to ask the question, at least with seeming propriety, whether it is absolutely necessary to adhere to the words of our best authors, supposing better words can be found to supply their place, or the same words be distributed in a better manner, always supported and exemplified by clear and definite descriptions? To depart from ancient rules, without judgment, leads to confusion and positive loss; but by carefully copying nature, and naming things according to their real use, structure, or connexions, without revering too much or despising the opinions of antiquity, often simplifies ideas, and is the only true way to reach something like certainty of knowledge.

Yours with respect,

J. A. H.

May 1, 1830.

SKETCH OF THE PROFESSIONAL CHARACTER

OF THE

LATE WILLIAM LISTER, M.D.

Formerly Physician to St. Thomas's Hospital.

THIS estimable physician, after maintaining a deservedly high reputation in this metropolis for nearly half a century, died at his house in Lincoln's Inn Fields, on the 3d of January, 1830, aged seventy-three years.

Dr. Lister possessed an acute and vigorous understanding, which had early received the culture of a liberal and extended education. His deep and solid attainments, both in philosophy and in the classics, formed an admirable basis

for studies more directly of a professional nature. These he afterwards pursued in the university of Edinburgh, with such persevering ardour and success as to acquire a high character for his knowledge of medicine and the collateral sciences. He took an extensive range in study, and always continued to retain an attachment to general science; and it is worthy of remark that, to the very last, he continued to keep pace with the improvements of the day, and even in chemistry to make himself intimately acquainted with the rapid progress of discovery. So great a love also did he cherish for classical literature, that, until within a short time of his death, he was accustomed, in the intervals of professional duty, to which he conscientiously devoted a large portion of his time and energy, to recreate himself with the poets and historians of Greece and Rome. Nor did he discover any diminution of interest in the science of mind, on which he continued to read with the same deep attention and eager spirit of inquiry which had characterized the investigations of his early collegiate life.

Notwithstanding, however, this steady attachment to general science and literature, in which his acquirements were not less extensive than profound, Dr. Lister constantly made his profession the principal object of attention. Few individuals, perhaps, have possessed a constitution of mind better adapted for the prosecution of medical inquiry. An acute perception and great power of attention were united with a sound and discriminating judgment, by which he was enabled to view a subject in all its bearings, carefully separating what was essential from that which was merely accidental and adventitious, and generally deducing from the whole a correct and logical conclusion. So thoroughly and patiently, indeed, did this indefatigable physician investigate the more obscure forms of disease, as seldom to have occasion to amend his opinion or retrace his steps. Like his intimate friends, Dr. Baillie and Mr. Cline, he was accustomed to express his view of a case in a few clear, forcible words, and in a manner simple and unadorned, yet calculated to impress the hearer with a conviction of the value and correctness of the opinion.

Dr. Lister's practice exactly corresponded with the clearness and decision

of his mind, evincing an equal degree of simplicity and of energy; and thus enabling him to ascertain, with considerable accuracy, the progress of the disease and the effects of the remedies.

Nor would it be proper to omit a special reference to those sterling moral qualities, which were not less conspicuous and influential than his intellectual endowments. Uncompromising integrity and genuine disinterestedness, were strikingly observable in his whole character. The welfare of his patients and friends, rather than his own individual interest, appeared to be the predominating principle of action. He had a just conception of what belonged to the character of a physician, and always maintained, by example as well as by precept, the dignity and value of his honourable profession.

With such principles and such conduct, it is not surprising that Dr. Lister should have inspired, in the minds of those who had the privilege of his friendship, a high degree of respect and attachment; although, from a rooted aversion to every thing like pretension and display, his manner may have appeared to strangers cool and unattractive. Those, however, who knew him intimately had abundant proofs of the tenderness and depth of his feelings.

With a mind so well stored and disciplined, and with opportunities and habits of observation so favourable to research, it is to be regretted that Dr. Lister should have written comparatively little. The specimens of biography given in the *Gentleman's Magazine* for November 1817, and October 1823, containing short memorials of two of his most beloved and intimate associates, viz. Dr. Wells and Dr. Baillie, sufficiently prove how admirably he was qualified for literary undertakings.

But to the most able and diligent, as well as to others, "there is a time to die." Dr. Lister contemplated that important change with remarkable composure. During the last thirty years of his life, indeed, he had suffered repeated attacks of angina pectoris, and had a constant persuasion of being himself the subject of organic disease about the heart. Of this settled and deliberate conviction he could not divest his mind, notwithstanding the remonstrances of his brethren, especially of his intimate friend Dr. Wells, who laboured to per-

suade him he was merely hypochondriacal: yet the post-mortem appearances decisively prove that Dr. Lister's usual judgment did not forsake him even in the consideration of his own individual case.

Among the papers examined after his death, a memorandum was found, dated December 20, 1821, in which he details the principal symptoms of his complaint, and his opinion of their nature, concluding with the following direction: "To ascertain the truth of the above conjecture, and to recommend the practice of post-mortem examinations by an example in my own person, I desire that my excellent friend, Mr. J. H. Green, may be requested to make a complete examination of me as soon after my death as he thinks desirable, and to furnish my son Nathaniel* with a statement of all he observes." In accordance with this request, an accurate inspection was made by Mr. Green, which remarkably confirmed the opinion which the deceased had entertained of the nature of his disease. The valves of the aorta, as well as various portions of the aorta itself, were ossified, as were also the coronary arteries. The mitral valves were also partially ossified, and the tricuspid passing into the same state. There was hypertrophy of the left ventricle; and adhesions had formed between the heart and pericardium. A large quantity of serum was contained in the cavities of the pleura. The internal carotid arteries were ossified, and the vertebral arteries thickened.

Notwithstanding occasional paroxysms of agonizing pain, Dr. Lister steadily pursued his usual avocations, and actually visited his patients until two days preceding his death. He had suffered, however, exceedingly during the severe weather of January last, both from difficulty of breathing and general uneasiness about his chest. Towards the evening of Tuesday, symptoms of effusion more distinctly appeared; and on the morning of Wednesday, surrounded by his numerous and affectionate family, and in the full possession of his mind, this venerable man gradually ceased to breathe.—*Med. and Phys. Jour.*

MEDICAL GAZETTE.

Saturday, May 8, 1830.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."—CICERO.

FAILURE OF THE MEDICAL DINNER.

THERE are few things more annoying in their way than for some notorious character—a bankrupt in reputation, a kind of person whom all the world avoids—to persecute you with his particular notice, and take all public opportunities of inflicting upon you his undesired acquaintance, firmly determined not to understand your numerous demonstrations of wishing to get rid of him. Precisely such a bore is a certain contemporary of ours to that portion of the profession called general practitioners. It is impossible to imagine any thing more persecuting than the systematic impertinence with which they are treated by their *soi-disant* champion.

It will be remembered, that soon after the decision by which a jury sanctioned the charge of a general practitioner for his attendance, it was announced that this event was to be celebrated in some public manner; and, after due deliberation, it was resolved that a dinner was the most eligible method of accomplishing the desired object. The announcement of this intention was no sooner made than we saw, from a variety of circumstantial evidence, that it was a trick of Wakley's, to bring about a radical meeting, in lieu of that which so egregiously failed about eighteen months ago. Such being our conviction, we felt it to be our duty to caution the profession against it; which we did accordingly—first on general principles (see Gazette, Feb. 20), and subsequently on the additional ground of the mea-

* Then a student in Medicine, but now M.D.

sure having emanated from the neighbourhood of St. Clement's church (see Gazette, March 6th); on which last occasion our words were, "*probably the measure would not have succeeded at any rate; but the manner in which Wakley has endeavoured to identify himself with it, has ensured its failure.*" This has been fulfilled to the very letter; for not only have the general practitioners of the metropolis refused to come forward, but many of them have assigned the above as the specific grounds of their declining to do so.

As the measure is now set aside, and all intention of the dinner abandoned, we shall briefly point the circumstances which led us so confidently to assert that it was an attempt to convert a general and most important, into a party, and most insignificant question—from the advancing prospects of the general practitioner to the waning fortunes of the *Lancet*. In the first place, in that journal the proposal to celebrate the "victory" of Mr. Handey originated—not openly, but in the form of an anonymous letter, to which was appended a note of Editorial approbation. The next step consisted in the formation of a committee, who prepared papers for the signature of those who might be disposed to sanction some public measure on the occasion; and these, rather injudiciously, were sent *from the Lancet Office* to various medical booksellers, a circumstance which, coming to be known, prevented any signatures from being obtained. We stated this fact to put the public on their guard; and next morning the blank testimonial of the influence and popularity of the *Lancet* was suddenly removed from the quarter whence we were supposed—and erroneously supposed, to have obtained our information.

Alarm being felt lest our decided opposition should influence the profession, and conscious that any apparent con-

nexion with the *Lancet* would mar the plan, a new set of stewards was, after much difficulty, obtained, having among them several men of known respectability, who were misled into the belief that the Editor of the *Lancet* had no longer any concern in the measure; and who, as we shall presently explain, had other and more important objects in view than the mere parade of a public dinner. The name of Lambert was withdrawn, as not likely to benefit the cause; and though a few wolves remained, yet were they in sheep's clothing, well knowing the necessity of assuming some disguise for the accomplishment of their purpose. Loud and unmeasured were now the commendations of the *Lancet*: it was "the great medical dinner," which was to prove "an event of vast importance in medical politics," and to be present at which was "the bounden duty of every surgeon." In short, no means were left untried, no effort spared, to further the great design; no terms of eulogy were too warm for those who favoured it—no abuse too gross for those who were opposed to it. Still, however, the public were backward; the list of guests did not increase, and as the time drew near, misgivings sprung up in the "champion's" bosom: he began too late to feel that the general sense of the profession had been truly depicted in the pages of this journal, and that the dinner—would fail. Under these distressing convictions, our *respected* contemporary contrived rather a cunning mode of getting out of the dilemma; he publishes a list of toasts which were not to have been given, and out of this nonentity seeks cause of quarrel with his own abortive measure; and after months spent in furthering it by every means in his power, at length ends by asking, "What the devil is the dinner to be held for?" The trick, though dishonest, is ingenious, and we may say of it—"Se non e vero, e ben trovato." De-

sirous to divert attention from his own tergiversation, he hurries through all the hackneyed topics of abuse: we are told for the hundred-and-first time that the physicians and surgeons of these kingdoms, almost without exception, have entered into "base and malignant combinations" to injure the general practitioner and "screen their own black and murderous deeds," and a great deal of stuff besides, such as knaves only are accustomed to indite, and fools only to believe. Among these spurious toasts one is "the Medical Press," and we allude to this the rather as there is really much justice in the character drawn of it by our contemporary. Our readers we doubt not will concur with him and us in thinking, that among the conductors of the medical press are to be found some "*most venal, stupid, and malignant,*" who wield their pen "*in an infamous cause;*" being "*scoundrels, whose only object has been, for a paltry pittance, to destroy reputation,*" and that such constitute "*a villanous gang,*" whose conduct has been truly "*fiend-like.*" Such, gentle reader, is the character of certain among those who conduct the medical press in this country, and traced by the hand of one who is evidently acquainted with the secret workings in the minds of those to whom the description so remarkably applies. He further adds, that they are not worthy to blacken Mr. Wardrop's shoes; but on this point we are not prepared to speak positively: from the great experience of some of them in blackening characters, we should think them tolerably well fitted for the occupation alluded to—but this, with deference to our contemporary, who is more intimately acquainted with their merits.

But to return: up to the latest moment did our amiable Editor use every possible means to have a sufficient number of persons collected together to make a decent appearance; and by a

singular perversion in the result, secured his own defeat by the very efforts to obtain the victory. Latterly he appeared personally in the field; and those who before had wavered, hesitated no more. There was a general and avowed determination not to become mixed up in a proceeding from a participation in which, it was obvious, that disreputable persons could not be excluded. Galled by the humiliation, and writhing under the sense of exposure, our worthy made a merit of necessity, and, at the eleventh hour, abused the dinner, to throw dust in the eyes of his readers, and make some innocent souls believe that *he* prevented it by withdrawing his patronage. He tells us, with amusing gravity, that the public has been in a state of "intense excitement" regarding this same dinner; the origin, progress, and abandonment of which they have viewed with the most absolute apathy. But we beg his pardon: though not *the* dinner, there is still to be *a* dinner. The matter, we are told, has assumed "a new character." Mr. Hume is to be supported by Mr. O'Connell, and "*other influential members of the House of Commons!!!*" Mr. Cobbett, we presume, will also honour the meeting with his presence, and return thanks for the compliments paid him in the *Lancet*. If this attempt should be persevered in, we should like to see who of our profession will be bold enough to go; who so beggared in reputation as openly to avow that he can be no farther lowered; or who with a name so bright that even this act of infamy would not stain it.

Meantime, we have only to add farther, that the stewards, finding the day previous to that on which the dinner was to be held, that only fifty persons could be calculated upon altogether, waited upon Mr. Hume, who advised them to give up the measure entirely, under such unpromising circumstances. This they accordingly did, but dined together on the appointed day, making,

with some friends, a party of about twenty, when the nucleus was formed of an association for the advancement of their mutual interests, which, if well conducted, may prove of infinitely more service than any thing which could have resulted from a public dinner, even had it been as pre-eminently successful as its failure, owing to the mar-plot with whom it originated, has been conspicuous.

After the above was printed, and while this sheet was passing the press, we received a Letter from one of the late Stewards, which will be found at page 224.

REFUSAL OF A PHYSICIAN TO GIVE HIS OPINION IN A CASE OF ALLEDGED INSANITY.

NOT many days ago the Lord Chancellor applied to one of the most eminent physicians at the west end of the town for his opinion in a case of alledged insanity, when the doctor positively declined having any thing whatever to do with it, declaring his determination to be founded on the unjustifiable manner in which the lawyers treated those physicians who endeavoured to afford the legal authorities all the information they could in the case of Mr. Davies. This is as it should be, and a few such refusals would bring the gentlemen of the long robe to their senses on this point.

THE KING'S HEALTH.

NOTHING can be more contradictory, or probably for the most part more incorrect, than the rumours in circulation with regard to the state of his Majesty. We have reason to believe that the statement lately made in the newspapers, that the disease was *angina pectoris*, is wholly unfounded. This form of complaint,

our readers are aware, is one marked by excruciating agony in the region of the heart, and dread of instant death—a species of suffering which we are happy in believing his Majesty has been spared. Neither, we imagine, is there any ground for the idea that effusion has taken place into the chest. Such an occurrence would give rise to permanent difficulty of breathing, whereas the impediment of the function assumes an intermittent form, coming on in paroxysms, during which the heart's action is irregular. At other times—and that is during the intervals—the breathing is quiet and the pulse natural. We understand too that his Majesty is able to lie on the back as well as on either side, circumstances strongly militating against the idea of hydrothorax. Considerable doses of Hoffman's anodyne, and opiates, have been administered, which would imply that his medical attendants regard the affection as of a spasmodic character. These have afforded considerable relief, generally producing free perspiration.

While any irregularity in the heart's action and any impediment to the function of breathing continue, it would be absurd to say that the case can be free from danger, or that the risk of sudden change is not to be kept in mind. At the same time there is no evidence afforded by any thing which has become known that organic disease—if present at all—has occurred to such an extent as necessarily to lead to an unfavourable termination. The public have an idea that organic disease of the heart is incompatible with life, whereas individuals may, and often do live, for many years after extensive changes of structure had occurred.

COLLEGE OF PHYSICIANS,

Monday, May 3.

THE chair this evening was taken by Dr. Roberts, when a paper was read by the registrar, Dr. F. Hawkins, consisting of

“Observations on the Blood, by William Stevens, M.D.”

The author remarked that there is often, in the West Indies, a malignant form of yellow fever, in which it is obvious, from the symptoms during life,

* A list of toasts, &c. was forwarded to us by the stewards. Except to correct the misrepresentations of the *Lancet*, these appeared to us not to possess sufficient importance for publication. The intended object has, we conceive, been accomplished by the remarks in the preceding article.

as well as from the appearances presented after death, that the disease has had its chief seat in the fluids. The cause of death, he thinks, under such circumstances, only becomes apparent when we open the heart and observe its contents. In this we find "a dissolved fluid," in place of blood; which is black as ink, and unfit for the purposes of life. These and various other circumstances induced Dr. Stevens to pay particular attention to the blood, and to make a number of experiments upon it, the results of which we subjoin.

The importance of the blood, and of the changes which it presents, have been comparatively neglected for nearly a century; and to this the author attributes the assumed fact of our "going back" in the theory of fever, at a time when such brilliant discoveries have been making in other departments of medical science. On examining the blood of those who had died of yellow fever, the following changes presented themselves.

1. It was more fluid than natural; a circumstance partly attributed to an excess of serum and partly to the fibrin not being found in its usual quantity. Besides this, the colouring matter was observed to be frequently detached from the globules, and dissolved in the serum; nor can this colouring matter be separated from the serum by filtration, or any other mechanical means. As the disease advances, however, the red colour is lost, and the whole circulating current becomes black, as well as thin.

2. The whole mass of blood, both in the arteries and veins, was changed to this black colour. Dr. S. has often taken black vomit from the stomach, and blood from the heart, and these have resembled each other so much as to render it almost impossible to distinguish them.

3. In bad fevers the saline matter appears to be exhausted faster than it enters the circulation; the blood losing its saline taste—of which circumstance the black colour is found to be a certain proof.

4. The blood, though dissolved, is not putrid; but dissolution is regarded by the author as the first step in the putrefactive process. Such dissolved state is held to be the cause, and not the consequence of death; being sometimes present during life. But it is stated to be the effect, not the cause of fever. Now, as this dissolved condition is re-

garded by Dr. Stevens as being frequently the sole cause of the fatal termination, so it became an object with him to discover some agent capable of preventing this change.

Saline matters, it is observed, are generally antiseptic;—during fever they are diminished in quantity; and hence it was thought that their administration, in the form of medicine, might be advantageous. Accordingly this was done; and, after repeated trials, the author became convinced that, when properly administered, they have "a specific effect" in preventing the dissolution of the blood.

Witnessing these results, and recollecting that various neutral salts pass into the circulation unchanged, Dr. Stevens was led to try what effect would be produced when these and other substances were mixed with the blood while it was yet warm and fluid*. The results were, 1st, that acids, as a general rule, rendered the blood darker; and this in proportion to their strength. When any of the strong acids was mixed with a little water, and added to recently drawn blood, this immediately became changed from red to black. Even the vegetable acids produce this effect.

2dly. The pure alkalies produce a similar change, though not in so remarkable a degree.

3dly. The neutral salts immediately give to venous blood a bright scarlet colour. This effect likewise resulting although the alkali might be a little in excess, as in the subcarbonate of soda.

4thly. Even the black and morbidly attenuated blood taken from the heart in fatal cases of yellow fever, was similarly changed into a bright red fluid by the addition of neutral salts.

Dr. Stevens proceeded to state, that he intended to enter on the subject more fully in a work which he is about to publish; when he will endeavour to prove that black is the natural hue of the colouring principle of the blood—and that the various properties resident in blood depend on the quantity and condition of its saline impregnation.

In drawing his inferences, the Doctor argued, that, in violent fevers, even when proper means are used, chemical changes nevertheless frequently take place in the circulating fluids, and that

* The best mode of conducting this experiment is to mix the agent so employed with a little water, and add to it the blood before it coagulates.

these changes "are almost always the sole cause of the mortality." The deterioration of the blood, in the fevers of hot climates, is said to be very obvious, and to occur in the milder forms of the disease witnessed in this country, as proved by the experiments of Dr. R. Clanny, of Sunderland.

As the counterpart of this, it is held, that when efficient means are used "to protect the organs" during the early stage, and proper diet and saline medicines are subsequently exhibited, the bad symptoms are generally warded off. These are supposed to act chiefly by preventing the "dissolution" of the blood till the fever abates and the danger is gone. A method of treatment, founded on these views, is stated to have been remarkably successful, both in the hands of the author and others. Thus, fever prevailed at Trinidad in 1828: the patients were bled and purged freely at the commencement; then they had neutral salts; during their convalescence, quina; and one of Dr. Stevens's correspondents, Mr. Greatrex, stated, that of 340 cases so treated not one proved fatal. On the contrary, emetics, calomel, antimony, opium, and acids, are represented as increasing the evils they are intended to relieve; and, in fact, as greatly augmenting the rate of mortality in the fevers of hot climates. The Rochelle salt, and the carbonate of soda, were particularly mentioned by Dr. Stevens, though not to the exclusion of "other active saline medicines;" and, in conclusion, he stated that since the treatment above alluded to had been adopted, the yellow fever had been in a great measure disarmed of its terrors.

ROYAL INSTITUTION*,

Friday, April 30, 1830.

WHITLOCK NICHOLL, M.D. VICE-PRESIDENT,
IN THE CHAIR.

Descent from Mont Blanc.

DR. EDMUND CLARK, who last season gave a very amusing account of his ascent of Mont Blanc, this evening proposed to describe his descent. It was,

however, rather a mineralogical dissertation, and its chief interest depended on numerous specimens brought from different parts of the mountain, which cannot be described in a report. He contended that the rocks should be considered *granitic*, rather than *granite*; and, to familiarize the altitude to travellers at home, gave several somewhat novel computations—such as raising the monument to seventy-six times its present height, or piling St. Paul's upon itself thirty-nine times, or both the monument and the cathedral twenty-six times; which would then about equal the height of the mountain, it being, according to several admeasurements, from 15,752 to 15,772 feet above the level of the sea. The Doctor particularly recommended all future travellers to take only *unmarried men* as guides, that, if an accident such as happened to him should occur—for several of his guides were buried in an avalanche—the consequences of the misfortune would be less extensively distressing.

In the Library there were several cameleons, and other interesting specimens of natural history; especially the horn of a rhinoceros, upwards of three feet in length.

UNIVERSITY OF LONDON.

MEDICAL DIPLOMA.

To the Editor of the London Medical Gazette.
(With the Warden's compliments.)

IN the "Second Statement by the Council," published before the opening of the University in 1828, it is announced that, "besides certificates of the professors, the University will grant certificates of general proficiency in literature and science. Every student will be required to produce a certain number of professors' certificates, before he can be allowed to enter upon the examination of the general certificate."

The object in granting this certificate is, to put the student in possession of a document which shall be an evidence of his having acquired at the University a certain amount of knowledge in the different departments of general and professional education. But to make the document practically useful, it must have such a *designation* as the person obtaining it can conveniently affix to his name, and be called by; as is the case when he takes a degree at an incorporated university.

* ERRATUM.—In our last report, page 182, col. 2, line 35, for "twist," read "burst."

The Council have been for some time engaged in considering the qualifications, conditions, and the form, under which this diploma shall be granted in the different departments of education; they have not yet settled what these shall be in any other than the medical school, but expect to be able to announce the whole scheme before the conclusion of the present session. Having come to a decision upon the medical diploma, the Council have thought it advisable to make it known before the medical students of the present session shall be dispersed.

It has been resolved that the general University certificate shall be granted, in the medical school, under the following conditions and regulations, and that it shall be called "*The Diploma of Master of Medicine and Surgery in the University of London*," (which may be thus translated and abbreviated, "*M. Med. et Chir. U. L.*")

1. That the candidate shall be twenty-one years of age.

2. That he shall have attended lectures on professional subjects, during three academical sessions of this University; or two sessions at this University; and one winter session of at least five months' duration in any established school at home or abroad.

3. That he shall have acquired certificates of honour* in the following classes in the University:—

Practice of Medicine, Anatomy, Physiology, Surgery, Midwifery, and Dis- eases of Women and Children,	Materia Medica, Botany, Chemistry, and Anatomical Demon- strations and Dis- sections.
--	---

4. That in the year which may be spent out of the University, he shall have attended lectures on two different professional subjects, each course of such lectures being of at least five months' duration.

5. That he shall have attended the medical practice of an hospital, containing at least 100 beds, for twelve months; and the surgical practice of the same hospital, or another hospital of the same number of beds, for the like period of twelve months.

6. That he shall be required to translate a passage in writing from Celsus, Gregory, Heberden, or other Latin medical author.

7. That having complied with the preceding regulations, he shall write an Essay in the English language on some professional

subject, chosen by himself, and approved of by the Faculty of Medicine before the Essay is composed. That this Essay shall be read in whole or in part, as the Faculty may desire, at a public meeting in the University; and that the candidate shall be called upon to explain or defend the doctrines maintained in his Essay. That he shall also make an anatomical demonstration, and be examined upon any part of his professional studies on which the Faculty of Medicine may think proper to propose questions.

In proposing the above regulations for conferring an honorary distinction suited to surgeons and general practitioners, the Council have thought it proper to require attendance on those classes only which are necessary for obtaining the diploma of the College of Surgeons of London and Society of Apothecaries. But they are desirous that the attention of medical students should also be particularly directed to the subjects of *Clinical Medicine*—*Comparative Anatomy*—and *Medical Jurisprudence*; and it will also be a great recommendation to candidates that they should possess some knowledge of *Mathematics*—*Natural Philosophy*—and *Natural History*. The scheme of instruction in the University affords ample opportunity for such studies; and a diligent pupil, during the period prescribed by the regulations, may obtain respectable knowledge in several of these departments, without interfering with the more direct object of his pursuits.

The diploma will be conferred in public on the 23d of December in each year, or the 22d, if the 23d be a Sunday; and the examinations will commence on the corresponding day of the preceding week. The Essay must be sent to the Secretary of the Faculty of Medicine on or before the 15th of November, and must be signed by the candidate, with a declaration that it is wholly his own composition. In the event of students leaving England, or in other cases of emergency, the diploma will be granted at other periods of the session, if the candidates possess the necessary qualifications.

In selecting the designation, care has been taken to avoid all interference with the titles and privileges conferred by chartered bodies. The value of the diploma to the possessor of it will depend upon its being known to be granted to those only who, after a strict examination, prove themselves worthy of such a distinction.

The following extract from a report of the Faculty of Medicine, contains their views as to the good effects upon the education of medical students which this measure may tend to produce.

"The medical profession is divided into

* It is proper to explain to those unacquainted with the system of the University, that certificates of honour are granted at the conclusion of each session to the more distinguished students in the several classes. The distinction is conferred, if answers in writing to questions proposed during a very carefully conducted examination, shall prove that the student must have diligently attended to the instruction of the professor.

three classes : viz. physicians, surgeons, and general practitioners. The latter form by far the greater body, and until this University can give a physician's degree, not many of those destined for that branch of the profession can be expected to take any considerable part of their education in its medical school.

"Under the appellation of general practitioners are included two distinct classes of medical men. One of these consists of practitioners who hold a highly respectable rank in the profession, and who have devoted much time, labour, and money to their professional education ; men possessed of some attainments in the collateral sciences, and who, practising their profession in a liberal and scientific spirit, have the highest claim to the confidence of the public. Another class bearing the same appellation, consists of those who have acquired the right to practise by possessing only the *minimum* of knowledge by which the licence can be obtained, earned by the smallest possible expenditure of time and labour, and who consequently have very imperfect professional attainments. The public possess so little knowledge of the details of a medical and surgical education, that all the most serious duties of the profession are commonly confided, without inquiry, to any one who calls himself a general practitioner, and to such hands, especially in the country, the largest portion of professional duty and responsibility is intrusted.

"It becomes, therefore, a great duty for the University to endeavour to remedy the evil, as far as it has the means of doing so, by holding out this honorary distinction as encouragement to general practitioners to follow such a more extended course of study as the science they profess, and as the public interest require."

(By order of the Council,)

LEONARD HORNER, Warden.

University of London,
24th April, 1830.

HOSPITAL REPORTS.

ST. GEORGE'S HOSPITAL.

Compound Fracture of the Leg, accompanied by Delirium Traumaticum, treated with large doses of Opium.

J. R. 45 years of age, was admitted into St. George's Hospital on the evening of the 6th of November last, under the care of Mr. Keate, with fracture of both bones of the left leg. The tibia was broken just below its centre, and badly comminuted. The compresses were soaked with blood, which had escaped from a small wound situated over

the fracture, and now scarcely perceptible. The skin in the neighbourhood was thin and dark-coloured, with several small vesications. The fracture of the fibula was at its upper part. The whole limb was swelled to a large size, partly from effused blood, but chiefly from oedema. The opposite leg was also cedematous.

The accident happened on the preceding evening, a few miles from town, and was produced by his attempting, when in a state of intoxication, to get on a coach, which was moving at a rapid pace. One of the wheels is said to have struck the limb, but not to have passed over it.

His general appearance was very unfavourable, the complexion being sallow, interspersed with spots of *aene rosacea*: his sharp sunken eye, with the *areus senilis*, his scanty grey hairs, and trembling hand, bespoke premature old age. He must once have been a stout man, but was now thin, and of a relaxed fibre. He stated himself to have been a wine and spirit merchant, in respectable circumstances, and confessed that he was addicted to the immoderate use of both spirituous and fermented liquors; that he had been occasionally the subject of gout; and, judging from his own account, had once or twice suffered from symptoms resembling *delirium tremens*; notwithstanding which he described his general health as being tolerably good. Since the accident he had suffered from troublesome diarrhoea, and had had no sleep. The pulse was 86 and steady; skin cool; tongue furred in the centre, but moist; leg not very painful. Limb placed in a junk; to be kept wet with a strong camphorated spirit lotion, and he was ordered—

Liq. Opii Sedativ. ℥l. ex haust.

Camph. ʒiiss. statim.

In two hours after, being restless, the draught was repeated, with ℥xxv. of the Liq. Opii.

8th.—Limb going on favourably. The wound has healed, and the appearance of the skin has greatly improved; the diarrhoea has ceased. He has been taking the following draught every six hours:—

Liq. Opii Sedat. ℥xxx. Ammon. Carbon: gr. vj. Mist. Camph. ʒiiss.

His nourishment has consisted of beef tea, arrow root, &c. Has had little or no sleep since his admission. To repeat the draught, with an increase of ℥xx at bed time, and to have ʒ oz. of gin daily. of the Liq. Opii.

9th.—Last night he became very restless, tossing about in and attempting to get out of bed, and talking much of law business in which he was concerned, but when spoken to answered rationally. The pulse became less steady in its beat and quicker; some strong gin and water was given him and a double dose of opium; he slept a little towards

morning, but even then he kept constantly moving the limb about in bed. He is to-day much more composed, but quick and irritable in his manner. Pulse upwards of 100; tongue furred; bowels confined; the limb to be placed in Amesbury's apparatus. To repeat the draught of liq. opii sed. with a drachm dose at bed-time, and to have 6 oz. of gin daily.

10th.—Another restless night and no sleep; the bowels have acted freely from opening medicine. He states that he has been in the habit when not well of occasionally taking the tinct. opii in drachm doses. To continue the draught every 6 hours, with a drachm of liq. opii sed. in each.

11th.—Last night the delirium and restlessness greatly increased, and in the absence of the nurse he got out of bed and began to dress himself. On being spoken to his answers were quite rational, although his manner was extremely quick and irritable. Pulse to-day 96, of sufficient strength; bowels open; tongue clean; leg looking well; the bones are kept in good apposition by the apparatus in spite of his constant motion.

12th.—Last night the delirium, &c. became worse than ever, and he was with difficulty kept in bed. At 11 p.m. three grs. of the ext. opii were given him, and repeated at intervals of two or three hours. During the night he took grs. ix. of opium, which did not procure him any sleep. To-day the pulse is 100; tongue a little furred; the leg more swelled.

To discontinue the six-hour draught, and to take every two hours three grs. of the ext. opii.

9, p.m.—Having taken two doses without any effect, grs. iv. of the powdered opium, with gr. $\frac{1}{4}$ of ant. tart. were administered, and lbj. of porter was given him, soon after which he fell asleep, and slept soundly for several hours, during which time both hands and legs were observed to be constantly in motion, and he sometimes struck one side of the face with one hand and the other side with the other for a minute together without awakening, and made other odd gestures.

13th.—Last night, at 10 p.m. he took one five-grain dose of pulv. opii, soon after which he fell asleep and slept soundly the whole night; he is to-day much better, but very irritable. Pulse 100; tongue furred; bowels confined; leg doing well, but of a large size; fluctuation of fluid to be felt over the fracture. To continue the gin, porter, &c.

14th, 8 A.M.—Since yesterday he has taken xij. grs. of pulv. opii, but has not once slept, and passed a very restless night, but is in other respects the same.

To have Oss. Gin daily, to continue the Porter, and to take the Opium in vij. gr. doses.

15th.—Up to ten o'clock last night he had taken during the day xxviij. grs. of pulv. opii; was now given a ten-grain dose, but he passed a sleepless night, although quieter than the last. To-day, however, he is very restless, with constant starting of the limb, which he says is produced by some one striking him violently on the calf of the leg, with a stick or stone. Talks sensibly, but wanders at times. Pulse 90; tongue furred; bowels open. It was now directed that he should take one gr. of the acetate of morphia every two hours. The stimuli to be continued.

16th, 10 A.M.—Since yesterday morning he has taken ix. gr. of the morphia, without any effect, his night having been worse than any since his admission; the delirium, &c. being constant. The leg is doing tolerably well, although the bones have been a little displaced by his jumping out of bed; fluid over the fracture becoming absorbed.

Rep. Gin, Porter, &c.

N. B.—The acetate of morphia is known to be good, having been procured at Mr. Garden's, in Oxford-Street.

17th.—Up to six o'clock last evening, he had taken a scruple of powdered opium, and a drachm of the tinct. opii had been given by the rectum, but he remained as restless as ever. He now took a scruple dose of crude opium, soon after which he fell asleep, and continued to sleep soundly for five or six hours. To-day he is quite a different man, being much less irritable, &c. Pulse 90, wanting power; bowels open. The fluid over the fracture has become absorbed. The leg is doing well, but becomes so much swelled towards night as to require all the straps of the apparatus to be loosened.

To take the Gin as usual, with lbij. of Porter, and meat diet.

18th.—Towards evening delirium came on, with great restlessness. A scruple of crude opium was given him, but not producing any effect, x. grs. more were administered, after which he slept soundly for many hours, and is to-day better than he has ever been since his admission.

19th.—Took a scruple of crude opium last night in two doses, and slept well. Leg going on favourably. Much less starting of the limb.

20th.—An attempt was made last night to reduce the dose of opium to xiv. grs., but he became very restless, and it was found necessary to give half a scruple more; after which he slept tolerably well, but is more irritable in his manner to-day.

22d.—For the last two nights he has taken each night a scruple of the crude opium, and has rested well. This has always been given in two doses, the second not being given till his restlessness, &c. required that it

should be administered. Leg examined, and union found to be very considerably advanced.

24th.—Not quite so well, and last night he took ʒss. of the crude opium before sleep could be produced. He yesterday began to complain of pain and stiffness about the right shoulder, but nothing can be discovered in this situation to account for it: thinks himself that it is rheumatic.

25th.—Since the last report he has continued to take a scruple dose of crude opium at bed-time, combined with a scruple of P. Ipecac. comp. The delirium has been very slight, but no sleep could be procured without the opiate. He still complains of the pain in the shoulder, which is now swelled and somewhat tender, but moving the arm does not produce pain; has had no rigors.

29th.—The tumor in front of the shoulder joint has increased to a large size, and fluctuation is distinct. No rigors, but considerable febrile disturbance. Has taken no opium since the evening of the 27th; no delirium; has rested tolerably well; leg going on as well as possible.

Ordered Bark, with the ammoniated tincture of Bark, every six hours. To take Oss. of red wine daily, with the porter and fish diet. Discontinued the gin.

Dec. 1st.—Abscess punctured, and a large quantity of well formed pus evacuated, which did not in any way communicate with the joint, but a probe passed to the under surface of the scapula. A poultice to the shoulder.

15th.—There has been no return of delirium, and he has only occasionally taken a small dose of tinct. opii. at bed-time. The discharge from the abscess has greatly diminished; the apparatus was removed from the leg ten days back, the bones having become well and firmly united; common splints applied; general health much improved. He continues to take the bark, wine, porter, &c.

On the 18th of January, the abscess having been healed up for some days, and the leg being quite strong, he was discharged cured.

N.B.—During the period at which he was taking the opium the bowels were not more confined than they would probably otherwise have been, and were easily acted on by ʒss. of *haust. sennæ*. On leaving off the opium he had a diarrhœa, which was restrained by the usual remedies.

EDINBURGH ROYAL INFIRMARY.

Enlargement of the Knee—Abscess communicating with the Joint—Poultices and rest, followed by the application of plaisters and bandaging—Recovery.

ROBERT WATSON, æt. 11, admitted under the care of Mr. Liston, February 4th. The right knee is enormously swollen, and the motion of the joint is almost entirely gone, the limb being in a state of semiflexion. The swelling is globular, soft, and elastic, and is the seat of frequent and acute pain. On the outside of the joint there is a narrow aperture, discharging thin purulent matter. His health is considerably impaired; Pulse 120; bowels regular.

States, that about fourteen days ago he sustained an injury of the knee by falling on a sharp pointed body; that this was followed with acute pain in the joint, and considerable swelling; and that an abscess formed and burst, giving rise to the above-mentioned fistulous aperture.

5th.—On introducing a probe, the opening is found to communicate with a large abscess, which evidently extends into the cavity of the knee-joint. The aperture was enlarged, and an incision made into the most prominent part of the swelling on the inside of the knee.

Poultices were afterwards applied, and the limb kept in a state of complete rest. The purulent discharge was at first profuse, but gradually diminished, and was followed by the escape of a considerable quantity of synovia.

On the 16th all inflammatory symptoms had abated, and the discharge had almost entirely ceased, but the swelling still continued to a very great extent. The knee was surrounded with plaister, and bandage, according to the plan of Mr. Scott, and a wooden splint was placed on the posterior part of the joint, in order to extend the limb.

On the 19th the dressings had become slack from diminution of the swelling; they were therefore removed, and similar ones applied.

By the 22d they had again loosened, and were reapplied. The swelling was found to be much diminished; the wounds on the inner side of the joint were nearly closed, and the limb was considerably extended.

March 12th.—The knee is now of the same dimensions as the other; the wounds have healed completely; and the patient enjoys the free use of his limb. Dismissed cured.

This case has been selected as an example of the speedy and satisfactory cure which in certain cases follows the above mode of treatment.

Melanotic Tumor of Eyeball—Extirpation—Cure.

John Maxwell, æt. 52, admitted under the care of Mr. Liston, February 16th. Enjoys no vision with the left eye. In the outer canthus are two small prominent tumors, of a shining appearance and black colour, appearing to be covered merely by the attenuated conjunctiva. A dark-coloured tumor also appears in the interior of the eye, not far distant from the cornea; the lens is opaque. The eyeball is somewhat protruded. He complains of slight pain in the eye, not constant, and of a lancinating kind.

States that the disease has been of about two years' duration, that he has never experienced much pain in the eye, and that its vision was lost at an early period of the affection. The cornea had ulcerated and the humours been discharged, but the aperture closed and the aqueous humour was regenerated.

17th.—To-day Mr. Liston removed the contents of the orbit, by means of a volsella and a straight bistoury. The hæmorrhage was very profuse, but was completely arrested by firmly and quickly stuffing the cavity with charpie, and retaining graduated compresses by a tightly applied bandage.

On examining the removed mass, several melanotic tumors, of the size of peas, invested by a delicate membrane, and of a shining appearance, were found embedded in the cellular tissue exterior to the ball of the eye. On making a section of the ball, melanotic matter was found extensively deposited in the posterior part, so as to form a firm solid tumor, leaving no trace of the retina and vitreous humour, and pushing forward the opaque crystalline lens into almost immediate contact with the cornea. The sclerotic coat was considerably thickened, and the surrounding cellular tissue much consolidated. There was great atrophy of the optic nerve, it being diminished in size, of a flattened form, and its neurilemal covering very loose.

18th.—Has passed a good night, and is free of complaint, except of slight pain in the wound. Pulse natural.

22d.—Has continued to do well. The wound has been dressed daily since the 20th, the charpie having been gradually removed. Purulent discharge from orbit, not profuse.

On the 26th, an attack of erysipelas occurred around the wound, and extended to the face and scalp. It was, however, subdued in the course of a few days, by the employment of punctures and warm fomentations externally, and of the solutio tartratis antimonii internally.

Afterwards no untoward symptom occurred, the orbit gradually filled with healthy granulations, and the patient was dismissed free of complaint on the 18th of March.

FINAL ABANDONMENT OF THE INTENDED DINNER—PROPOSED MEDICAL "ASSOCIATION."

To the Editor of the London Medical Gazette.

SIR,

I DEEM it expedient to acquaint you, and through the medium of your journal the medical public, that the stewards of the intended public dinner, judging from the paucity of the number of gentlemen who signified their intention to dine with them, that it was not a popular measure, have separated, and do not intend to resume their duties.

The stewards dined together on Saturday, to meet those gentlemen who might not have had notice of the postponement, and about twenty persons assembled. One of the intended objects to have been proposed at the dinner was attained at this small meeting,—the formation of an association, entitled "The Association of the General Medical Practitioner." As little else was done but giving the name and electing the officers and committee *pro temp.* I am enabled only to furnish you with a sketch of the general intentions of the Association. The first object is to bring general practitioners more directly in communication with each other, for information and for co-operation in any measures that may enhance their respectability, and be for their mutual benefit; embracing the most desirable of all objects—a fair and proper mode of remuneration, free from the trammels of trade, and enabling us to exercise our department of the profession with pleasure and credit to ourselves;—to form a Medical Society, and also a Journal, to publish the papers read and discussed at this Society;—to establish a fund to carry into effect the general measures, and to enable us to afford relief to the needy of our profession, and their dependants.

These, sir, are the chief principles of the society; and, I think, they are fair and legitimate objects—such as must meet the approbation of all our medical brethren. As I have not the permission of the gentlemen who subscribed their names to the Committee, to publish them, I cannot furnish you with them. I beg to say, however, that they are members of the profession, of whose acquaintance I feel proud.

I am, sir,

Your obedient servant,

JOHN LAVIES,

One of the late Stewards.

THE LONDON MEDICAL GAZETTE,

WEEKLY JOURNAL

OF
Medicine and the Collateral Sciences.

SATURDAY, MAY 15, 1830.

LECTURES ON SURGERY,

Delivered at St. Bartholomew's Hospital,

BY WILLIAM LAWRENCE, F.R.S.

— 149.
LECTURE XL.

Chilblain—Onychia and Paronychia—Nævi.

THAT peculiar inflammation of the skin, gentlemen, which is called in English *chilblain*, arises, as the name implies, from the action of cold upon the surface of the body, the affected part being *chilled*, or having the temperature reduced: the Latin name is *pernio*. As this is the result of the action of cold, it takes place in those parts of the body in which the circulation is the most feeble, that is to say, in those most remote from the heart—the fingers and toes, the heel, the extremities of the ear, and even of the nose. It also happens most frequently in young subjects, in whom the organization has not yet attained its full vigour, or power of resistance, to external influences. When I say that this arises from the application of cold, you must understand that it is not immediately produced by cold; it is necessary that the temperature of the part should be reduced by the application of cold, and that it should be subsequently heated; that there should be an alternation of heat and cold: it is in these circumstances that the origin of chilblain is to be found. Indeed, in general we observe that chilblains do not happen during the period of most intense frost; they are more frequent and more troublesome when the temperature of the atmosphere begins to be rendered milder by the subsequent thaw. It was observed by Larrey, in the winter campaign of the French in Russia and Poland, that for a few days before, and for a few days after the battle of Wagram, the thermometer was very low, from ten to fifteen degrees below zero—an intense cold; and yet during that time

there was no mortification, nor did any other particular suffering about the hands or feet occur. But about two days after the battle a thaw took place, the thermometer rose from eighteen to twenty degrees, and then a great number of cases of mortification of the feet occurred in the army in some particular divisions that were very much exposed, and nearly all the soldiers suffered more or less.

These circumstances lead us to the modes by which the occurrence of chilblain may be obviated. In the first place the extreme parts of the body in which there is a liability to have them chilled, should be warmly clothed. In the next place, when any part, such as the hand or foot, has been chilled, it should not be immediately exposed to that high temperature which the feeling of cold inclines persons to wish for at the moment: the hands or feet, for instance, should not be plunged in warm water, nor brought near the fire; on the contrary, means should be taken to restore the circulation gradually. The principal means of prevention consists in preserving the part from vicissitudes of heat and cold.

The affection which we call chilblain exists in various states—there are, in fact, different degrees of it. In the first, or milder form, we have simple inflammation of the skin—what nosologists call *erythema*, that is, mere redness and vascular congestion, without heat in the part;—there is, to be sure, connected with this some degree of effusion into the subjacent texture: thus the part is not only red but rather swelled. When the affection is very active, we find this is usually so considerable that the motions of the part are impeded. In the fingers, for instance, the whole of them may be so much swelled that the individual can hardly use them in writing, or in his ordinary occupations. There is a great sense of heat, a most troublesome itching and tingling, in conjunction with the redness and swelling;—these are the early symptoms of chilblain. Now the heat and itching are not constant during the

twenty-four hours; there is generally a particular period, as towards the evening, when the parts become warm, and then the heat and the itching are more particularly troublesome.

In the more active state of chilblains, relief of the heat and itching will be produced by cold applications of various kinds, but as people are possessed with the idea that chilblains are produced by cold, they do not like to use them; and common experience has established the fact, that applications of a stimulating kind are advantageous, and a great variety of these are popularly employed. Camphorated spirits, soap liniment, oil of turpentine, strong solutions of salt, and a variety of other stimulating things of that kind, are employed to rub the inflamed part, and with considerable benefit. The most effective application of this kind that I am acquainted with is one recommended by Mr. Wardrop, in a short paper that he has written on the subject of diseases of the toes and fingers, contained in the fifth volume of the *Medico Chirurgical Transactions*. It consists of six parts of soap liniment and one part of tinc. Cantharidis, with which the parts are to be rubbed two or three times in the twenty-four hours, and this generally removes the troublesome sensation of heat and itching.

In this condition of the chilblain we do not always find the part of a vivid red, but frequently find that the skin is very livid, of a dull leaden appearance, exhibiting in the colour a proof that the capillary circulation is very imperfect. After the inflammation has existed for some time, vesication will occur, and the skin will ulcerate, and this is the state which, in popular language, is called "broken chilblain." The cuticle becomes elevated into a livid or brownish vesicle, that is, there is a thin serous fluid, of a livid or brownish colour under it, and when this breaks the skin is observed to be of a dark or livid hue; it soon ulcerates, and the ulcer that is thus formed is of an unhealthy, unfavourable appearance, and particularly slow in healing. It has a greyish or brownish ulcerated surface, sometimes with bloody points interspersed, and with livid edges and surface, in which we see merely the existence of ulcerative absorption, without any attempt at repair. A soft poultice is the best application in the first instance to an ulcerated chilblain; and subsequently, in order to promote the restorative action, which is very deficient, you must employ local stimuli, and the two best are red precipitate, in the form of ointment, and nitrate of silver, in the state of solution.

There is a third and more serious effect of this kind, in which a part of the skin actually loses its vitality, and is converted into a slough. When a considerable part of the body is exposed to considerable cold you

have this effect—this sloughing extending to the whole of a member. The treatment here falls under the general principles that I mentioned to you in speaking of mortification.

Onychia and Paronychia.

Inflammation occurs sometimes (generally in consequence of injury to the integuments) at the extremity of the fingers or toes, and in their dorsal aspect at origin to the nail, and this has been technically called *onychia*. *Onyx* is the Greek word for nail, and *onychia* is inflammation of the part which forms and secretes the nail. This affection is attended with the formation of matter under the fold of the cuticle, which is reflected from the semilunar termination of the skin, and passes over the nail. Now this detachment of the skin from the root of the nail destroys it, and renders the formation of a fresh one necessary. The formation of matter sometimes extends under the nail, generally so that it becomes detached, and is no longer held in its situation except by its connexion with the cuticle at its circumference. In this state you easily detach it without giving pain to the patient, and this allows the new nail to form.

Matter may form in various parts about the nail, not immediately in the situation that I have mentioned to you, and these formations of matter are sometimes called *paronychia*:—*para* means near; *paronychia* means a formation of matter near the nail; it has also been called *panaris*, and by some writers, *panaritium* in Latin; and which, in English, is termed *whitlow*. In fact, there is no essential distinction between the several names of *panaris onychia*, *paronychia*, *panaritium*, and *whitlow*; they merely designate inflammation about the nail, or its neighbourhood.

When the integuments by the side of the nail become inflamed, either in consequence of being wounded, or from any other cause, and the cuticle is separated, which it soon becomes, it often happens that considerable pain and local inflammation are produced by the pressure of the hard edge of the nail against the denuded part of the skin. Under such circumstances it is not uncommon for a fungus to arise in that part of the skin that is the constant subject of this mechanical irritation; and in the various offices for which the fingers and toes are used, the part becomes pressed upon, so as to occasion a constant recurrence of pain. Thus great inconvenience is experienced from an apparently trifling cause; and under such circumstances it is expedient to introduce carefully, with the end of a probe, a fine thin piece of lint, which we commonly call the flue of lint, between the edge of the nail and the inflamed part of the skin on which it presses, so as to prevent the mechanical irritation,

and in that way you generally remedy the inconvenience. In the great toes of the feet a similar, but much more aggravated state of things, frequently arises in consequence of the pressure of tight shoes. The soft parts which are seated at the side of the nail, particularly on the inner side of the great toe, are pressed against it by a tight boot or shoe. They become irritated, inflamed, and thickened; and from some slight external injury a higher degree of inflammation is produced; matter forms; the skin becomes deprived of the cuticle, and then the same production of fungus that I have already mentioned arises; and this goes to such an extent that a considerable part of the nail towards the outer edge, and sometimes towards the inner edge also, is completely imbedded in it. This is what is called, in common language, the nail growing into the flesh, and what the French call *l'incarnation d'ongle*, which is a very similar expression.

Now a notion has been frequently entertained, that the state which I have just alluded to arises from some malformation or wrong direction of the nail; and thus the first curative efforts have generally been directed towards relieving or getting rid of the nail, or giving it what is considered a more proper direction. As these efforts proceed entirely on a wrong view of the cause, we cannot wonder that they fail to afford relief. The truth is, the nail is not at fault in these cases; the evil arises from pressure of the soft parts against the nail, and it is simply a state of things produced by mechanical irritation, from the constant pressure of the hard nail against the inflamed skin. A great point therefore, of course, whatever else you do, is to keep off the source of mischief—not to wear any covering that is tight, or produces pressure. In many instances, particularly those not of the worst kind, you can put a stop to the affection by simply attending to what I have mentioned, namely, introducing under the edge of the nail carefully, from day to day, or every two or three days, a portion of the soft part of lint. When you do this, you will understand that your object is to introduce simply a soft substance between the nail and the skin; and therefore you are not to use a considerable quantity of lint, and push it in forcibly, because that is likely to add to the mischief, but merely to put a bit of the softest part of lint gently under the edge of the nail, so as to prevent the source of irritation. Then, if you take care that the shoe is loose and easy, you generally find that this simple mode will remedy the inconvenience. There are instances, however, where the evil is too considerable to be got rid of in this way, and where it is found necessary to take away a portion of the nail; after which you can remedy the state of irritation and the fungus

of the skin: the nail which is reproduced will now take a proper direction; and the cause being removed, if you take care that the person does not wear tight shoes, the evil will not recur. Dupuytren recommends removing the part of the nail which presses upon the skin by means of a pair of scissors. The mode he recommends is this—to have a pair of pretty strong scissors, one part of which should be quite sharp; you put the sharp point under the edge of the nail, and then, by a quick motion, you carry it along the nail—that is, you thrust the sharp point under the nail where you wish to cut it through; and having cut it, you take a pair of strong forceps and tear off that part of the nail. This seems rather a rough mode of proceeding; however I have done it, and it is not found to be very painful—the pain is merely momentary. When you have thus got rid of the mechanical source of inconvenience, you probably find that the fungus and the thickened state of the skin will subside of themselves; if not, you may rub it gently with lunar caustic, and in proportion as the nail springs up again, you must pay some attention to see that it takes a proper direction. Now I am told there is another mode of taking away a portion of the nail that is equally effectual, but is not done in the same coarse and painful manner. Mr. Wardrop has informed me that a surgeon who resides at the west end of the town, and who practises particularly on the diseases of the nails, has observed that the nail rests in a bed of dense cuticle, and that therefore you can cut through the nail without actually cutting the *quick* so as to draw blood. The object is to make a perpendicular cut with a sharp instrument, something like a sharp penknife, through the nail; and then, he says, you can lift it out very easily from the bed of cuticle without giving pain, while you afford immediate relief. Of course, if you can do this, it is a more eligible mode of accomplishing the purpose. The mode by which people attempt to ease themselves, is by cutting away a piece of the edge of the nail; and certain methods have been proposed surgically for introducing a plate of metal under the edge of the nail, and by that means prevent it from pressing upon the skin. This notion is not at all founded upon a just view of the nature of the affection; and, I believe, is more calculated to add to the suffering of the patient, and to increase than to remedy it. Then, when the evil is remedied for the time, you prevent its recurrence by attending to the following circumstance:—The nails of the fingers are generally cut so as to form a semi-circular edge; but where the nail of the great-toe is affected in the way I have mentioned, it should be cut square—you should not cut away the angles. Thus the evil of allowing the nail to grow into the part is got rid of.

Nævi Materni.

Under the name of *nævi materni* are included various original deformities or peculiarities of the structure of some portion of the skin. The name *nævi materni*, which means simply mother's spots, is founded on the generally received notion that those peculiarities in the skin arise from some influence of the mind of the mother on the offspring. It has been supposed, for instance, that if a pregnant woman is terribly frightened by any strange sight, that the skin of the child will probably bear some mark on the body more or less allied to the object that has produced this terror. Or, again, if a pregnant woman should take a strong desire, or, as they sometimes call it, a longing for any thing, especially if the longing cannot be gratified, there is an idea that this object will be marked upon the child. Thus, if we may believe mothers and nurses, the objects that I am now going to speak of are only so many representations of things, whether of food or any thing else, that the mother has been longing for; whether it be beef or pork, raspberries or grapes, or the Lord knows what. This idea seems to be very prevalent: the same appearances are called in French *envies*, which means mother's longings;—the name they bear in German is the same—*mutter-mahl*, mother's spots.

We sometimes find an elevation of the skin, an irregular figure, of a rough granular surface, generally reddish, or brownish, or yellow, but varying in point of colour, and not uncommonly having on it particularly long hairs. These have been called in common language, *moles*; and they generally remain throughout life of their original size; they do not increase. It might happen that a mark of this kind was so situated as to produce a deformity; and if it is necessary you can remove it, the operation of extirpation being a very simple one. There are some instances of these elevations of the skin growing after birth, and attaining a large size, of which this specimen is an example.

[Mr. Lawrence here presented a preparation, observing, "this was cut from the lower part of the back of a lady, then an adult. It had been a 'mark' originally, and I do not know that I can give it any other name than that of a huge mole. It measures about one foot in length, and is about one foot in breadth. It had a bright red appearance during life. It was removed by Mr. Abernethy, and I assisted him in the operation, many years ago. It did not go deeper than the skin—this is the adipose substance under it."]

Sometimes a part of the skin is brownish, or reddish, and thickly covered with hairs, like the coat of an animal. A little time ago, I remember there was a boy in the

foul wards. I had him stripped to examine some syphilitic eruption. There was a part on the chest, about two inches one way and one inch the other, of light brown hair, like the coat of an animal. I looked at it, and said, "What is that on the chest?"—"Oh, sir," said he, "it is a mouse." I said, "it is not a mouse—it has no tail."—"Ah," said he again, "it had a tail, but somebody cut it off." I saw a curious looking child, a little time ago; a gentleman sent for me to see it as a curiosity. I think that a great part of the body was covered with hair. Over the lower extremities there was a great number of spots; one on the arm, and others on the trunk of the body. The skin covering the child, in other respects, was of the natural texture, and, indeed, these parts were not unhealthy.

In the greater number of these *nævi*, however, there is an unnatural state, particularly of the vessels of the skin. This peculiarity seems to consist more or less in the vascular tissue of the part. Sometimes you have a few vessels enlarged and ramifying superficially in the skin—sometimes giving not an inelegant kind of appearance. This has been called *spider nævus*—the ramifications bearing some analogy to the legs of a spider. Not uncommonly, you see parts of the skin discoloured—red, brown, or livid; sometimes of a deep tint, sometimes lighter, and this extending irregularly over a considerable part of the skin—very frequently on the face. These are commonly called *claret marks*, the colour being something like the stain produced by claret. You often see large vessels ramifying quite on the surface of the skin, and in some instances of that kind I have known individuals liable to occasional bursting of these vessels, and to very copious hæmorrhage from them. But these marks I am now speaking of generally are of a *stationary* kind; they do not increase; they remain in the same state through life. The *nævi* which are most commonly the subjects of surgical treatment, consist of peculiar vascular growths seated either in the skin itself, or in the adipose tissue immediately under it. The *cutaneous nævi*, or those seated in the skin, consist of a soft bright scarlet elevation, the surface of which is finely granulated. They appear to occupy a certain portion of the texture of the skin, as if a part of it were stained with this bright scarlet colour. It is really rather an elegant sort of texture which occupies the place of the natural structure of the skin; it is generally of a more or less circular figure, not rising high above the natural elevation of the skin. The *subcutaneous nævi* consist of soft swellings seated under the skin, imbedded in the adipose tissue, the skin itself being completely sound over them. Towards the centre of the *nævus*, you have more or less of a blue or livid appearance. It seems as

if some of the vessels were running out of the *nævus* to approach nearer the surface of the skin in the centre, so that you have a blue, or livid, or black discolouration in the centre, and a tumor extending in circumference under and much beyond the sound skin, in the cellular membrane beneath. This is quite a soft tumor. Not unfrequently, you have a portion of cutaneous *nævus* in the centre, and part of a *subcutaneous* tumor extending under it; so that, when we speak of cutaneous and subcutaneous *nævi*, you are not to suppose that they are so essentially different in their nature that they cannot be combined together. You have in these *nævi* one part which is a bright scarlet soft state of the skin, and another which forms a tumor under it. Both these kinds of swellings are soft and compressible; in fact, if you press upon them, you find that you diminish their bulk—that you squeeze something out of them; and when you remove the pressure, they slowly recover their former size. Sometimes they are rather firmer than the rest of the skin, and there is a sensible increase of heat in them.

These *nævi*, like the others that I have mentioned to you, may remain stationary—that is, you see them of a certain size at the birth of a child, or they acquire a certain size soon after, and then do not grow further. More commonly, however, they are small at the time of birth, and begin to increase, and often grow very rapidly for some time. With respect to those that are permanent, they do not always remain in the same condition. There are certain changes, according to the state of the system and the particular circumstances affecting the individual, so that growths of this kind will sometimes be more full and tense, the vessels being apparently more filled; at another time they are paler and more flaccid. There are the cutaneous *nævi*, which are sometimes compared to strawberries, raspberries, and so forth; and really the simile is not altogether inapt. I have many times been seriously told, and that by well-informed persons, that a certain mark on their daughter's back, which they call a raspberry, increases at the time that fruit comes in, and gets larger and generally redder by the time that raspberries are ripe. It then withers, shrinks, and disappears every year. It is these changes in the state of the *nævus* which have given rise to, and may support, this notion.

I mentioned to you that these *nævi* are usually small at the time of birth, and often, perhaps, so trifling as to be overlooked till some time after. Then they begin to increase in size, and grow rapidly. Thus you may see them of the size of a pin's head, or of the whole hand; indeed there is hardly any limit to their growth. They are most common on the head; frequently they are found on the scalp, and upon all

parts of the face; and sometimes they seem to occupy nearly the whole of a part—such as the ear, the eyelid, or the lip. I remember seeing the case of a young woman, at this hospital, where half of the lip and the corresponding part of the side of the face seemed to be entirely filled with this unnatural growth. It was covered by the skin externally, and by the mucous membrane of the mouth internally. These *nævi* are sometimes seated about the neck, often extending deeply;—they are more rarely seated upon the extremities of the body; sometimes they are found upon the trunk.

Those that grow consist essentially of large vessels near the surface, and it will happen frequently that these vessels will give way. They are liable to be ruptured by accident, and thus profuse hæmorrhage will take place, or sometimes, after attaining a certain size, a state of ulceration and inflammation comes on, and this ulceration, if it become extensive, will frequently destroy a considerable part of the morbid growth, and lead to a kind of partial natural cure of the affection. I have mentioned to you that pressure will diminish the size of the *nævi*, and that they recover their former magnitude when the pressure is removed. This effect is produced by squeezing the blood out of them; for what they contain, which is thus removed by pressure, is blood—and moreover it is arterial blood. In the cutaneous *nævus*, which is quite on the surface of the body, and where the vessels are covered only by a thin kind of cuticular integument, you have a bright scarlet tint, shewing that it is arterial blood. If the blood be in a deeper seated tumor, with a great thickness of integument over it, the colour is blue or livid, so that you might suppose that it was produced by venous blood; but you find, if you come to cut into such *nævi* in operations, that it is arterial blood which flows from them. I may mention to you, which is a further evidence of what they contain, that if an incision be made in operating—if you cut into any part of one of these growths, arterial blood flows out in a quantity and with a degree of violence that you can hardly imagine; and which you would scarcely believe possible unless you saw it. A copious stream of the most florid arterial blood comes out, and you cannot restrain it unless you press firmly on the whole of the surface that is injured by the incision.

When you come to make a section of a tumor of this kind after removing it, it exhibits a cellular appearance, and the general notion has been that it is made of cells, with large vessels ramifying through, and depositing blood in these cells. Now I believe this notion of the cellular structure of these *nævi* is not a correct one. So far as I have observed when a section is made, the apertures that are seen are the mouths of blood-ves-

sels; they are all regularly circular, with a smooth lining, like that of the blood-vessels. They appear to me, therefore, to consist essentially of an aggregation of vessels ramifying and combining together into a kind of tumor. Whether they be arteries or veins I do not undertake to determine, but I can only say that during life they appear to contain arterial blood, and when you cut into them, florid blood flows in the greatest profusion. Hence the name that is sometimes popularly given is by no means a bad one—*bloody tumors*, and they are described by Boyer under the title *tumeurs variqueuses*, which is the same as our popular term, and both of which designate that they depend materially on bloodvessels. Dupuytren has turned his attention to the structure of these *navi*, and his idea is, that they consist of the same kind of texture which is found naturally in certain parts of the body. Thus there are certain parts in which you find that the structures are usually flaccid, but which admit of distention by an increased influx of blood; they admit of the state which has been called *erection*, and the structure has been called by the French *tissue erectile*, *erectile tissue*, like that of the penis, the clitoris, the nipple of the female, and some other parts. Dupuytren considers that these *navi* are unnatural productions of erectile tissue in the parts in which they are found. Hence he has called them *tumeurs erectiles*. There are some points of analogy between these *navi* and the erectile tissue, but I must observe that we do not know quite enough of either of these two tissues thus compared to be prepared to assert or to deny their identity. I would observe, however, that this kind of structure not only exists as a congenital production, but may take place as an accidental formation after birth in various parts of the body. Under such circumstances, the tumor, although perhaps not precisely corresponding to the description that I have given to you, has, in many cases, another character, which is very important—that of pulsation,—having a pulsation synchronously with that of the arteries. This is a circumstance which I have not observed in *navi materni*, that is, in the congenital kind, and certainly does not exist in the greater number of them, though it has been sometimes observed. Dupuytren has alluded to it; he speaks of these tumors generally as having some pulsation. This is the affection which John Bell calls aneurism by anastomosis, and others have done the same after him. Hence it has been supposed that the congenital marks or *navi* are of this nature; but as I mentioned to you, they do not possess that particular feature upon which Mr. Bell founded his opinion, namely, pulsation, nor can these same growths be correctly denominated aneurism, for there is no kind of

analogy between vessels inosculating with each other as these do and that affection of the arterial trunks which we call aneurism.

The same principles of *treatment* are applicable to this affection whether it exists congenitally, as *nævus maternus*, or whether it is an accidental production taking place subsequent to birth.

If *navi materni* be stationary—if they do not increase in size, there can be no reason for interfering or meddling with them, unless they be so seated as to be a source of deformity; and as they are frequently found on the face, it may become desirable to remove them on this account, independently of the various mischief to which their increase might lead. A variety of methods have been proposed for dealing with these *navi*, when it is wished to reduce their size or to take them away altogether. Mr. Abernethy has given some observations on this subject. He observed the circumstance of their being occasionally of a higher temperature than the rest of the surface of the body, and therefore thought that if cold applications were used, so as to reduce the temperature, and then the part was subjected to pressure, they might be removed in that way. He mentions a case where an extensive *nævus* on the fore arm of a child was thus reduced. It must be observed, however, that we generally have to treat those that are seated on the face and head where pressure cannot well be applied; and besides, pressure is sometimes found to irritate them, and make them grow faster rather than to diminish them.

Excision is an obvious and at all events an effectual mode of getting rid of these affections. In cutting them out, you must observe the rule of taking away the whole of the unnatural growth; you must cut into the sound parts all round; you must not proceed economically, nor be inclined to save either skin or any other part in which any portion of this production may exist, because if you leave any thing behind, you have the growth reproduced, and if you cut into it in operating, you will have such profuse hæmorrhage that unless you saw it you would not think possible. You must cut freely in the circumference in the sound parts, so as to take away all the morbid growth, for although you have a good deal of hæmorrhage even in this way, yet you will not have that furious bleeding which results if you cut into the tumor. Very commonly in extirpating them, you have a degree of hæmorrhage which makes you think for the moment that the child (if the operation be performed on an infant) will die from the loss of so much blood. I may mention that the operation of excision on this account is in some measure limited to *navi* of a moderate size, for when the operation is performed on those of large size, there is really danger of immediate death

under the knife, from hæmorrhage. Mr. Wardrop took away a large nævus from the back of an infant; he took it away as quickly as he could, but it was one of considerable size, and there was a most profuse bleeding from the whole of the divided surface, and in about one or two minutes the child was defunct. On coming to examine this nævus, which he had so removed, one of the vessels that was opened was found to be of calibre enough to admit the largest writing quill. When you consider that the whole surface, perhaps, is covered with these vessels, and see how freely they emit their blood, you cannot wonder at such an occurrence.

In order to avoid the danger of hæmorrhage from the use of the knife, it has been proposed to tie these tumors,—to surround the base with a ligature, and draw it very tight, so as to produce mortification of the included part. In general the bases of these tumors are too large, and they are too little prominent to admit of surrounding them by a single ligature, but you pass under the base a strong needle with a double ligature, and when you cut off the needle you have two ligatures, which are to be tied one each way, so as to surround the base by two ligatures, each of which incloses one half. This is an effectual mode of preventing the danger of hæmorrhage. You might suppose that when the ligature surrounds a nævus of considerable size, and includes a large mass of integument, that this mode of proceeding might be liable to much inconvenience. I have operated, however, in a considerable number of cases, where the nævus was of considerable size, and I have in no instance seen inconvenience arising from the employment of the ligature. I have used it in cases where the nævus was so large that I dared not to extirpate it with the knife, and the operation has been successful, so that the proceeding seems to be a very safe one.

It has been proposed in nævus, as in aneurism by anastomosis, to prevent the growth of the tumor, and to produce its reduction, by tying the arterial trunks that feed it. Now in general we find that the vessels seem to come into them from all quarters, so that it is very difficult to do this. However, this has been more particularly attempted where the nævi have been seated upon the head, and where the carotid artery could be tied. Mr. Wardrop performed the operation of tying the carotid artery in a child for a large nævus on the head. This seemed to produce a considerable reduction in the size of the tumor; the child, however, was enfeebled and in a reduced state in consequence of partial ulceration and loss of blood from the nævus, and died more from that than from any other cause; so that in this case the effect of tying the artery could not be well estimated. In consequence of

this case of Mr. Wardrop, tying the carotid artery was tried by Dupuytren in a large nævus situated about the ear, and including the whole texture of the surrounding parts. By pressure on the carotid artery it was found that the size of the nævus was reduced, and that it became flaccid. Hence the natural inference was, that if the artery were tied, the nævus would be reduced in size. Dupuytren tied the common carotid artery, and for a few days the effect of the operation seemed to correspond with the wishes of the operator; the tumor became flaccid, but it soon swelled in size again, and after a little time it grew as fast as ever, so that in fact, according to the experience that we have at present, the plan of tying the arteries that go to these nævi, or the main trunks of the vessels which supply the part of the body in which they are situated, cannot be much relied on.

I remember a case of aneurism by anastomosis, seated on the finger of a young girl, on whom Mr. Hodgson operated. This was not a nævus—this was a production of the vascular kind, that came subsequently to birth, and formed a considerable swelling, occupying a great part of the finger, with a strong pulsation in it, and a degree of heat, not only in the finger, but in the whole hand. Mr. Hodgson tied the radial and ulnar arteries in that case, having first pressed upon them to see the effect, and having been satisfied that doing this materially reduced the tumor and stopped the pulsation. This operation was attended at the time with an interruption of the pulsation, and a reduction of the swelling; but the effect was only temporary, and, in fact, this girl suffered so much, that she wished me to do any other kind of operation that I could think of for her. I accordingly subsequently cut round the base of the tumor upon the finger—that is, I cut round the tumor between its basis and the hand, so as to divide the whole of the soft parts except the flexor and extensor tendons—and in doing this there was a pretty considerable hæmorrhage; for of course there was a necessity that all the enlarged vessels should be divided. This had the effect, I will not say of removing the tumor, but certainly of arresting its growth. I may mention that a question was entertained, if the skin were cut circularly round, and all the soft parts were divided except the tendons, whether or not mortification would occur. However, when I divided the vessels (I may mention that one of the digital arteries was as large as the radial artery), the arteries at the distal extremity, coming from the point of the finger, bled so freely, that I was obliged to tie some of them. The circulation in the small vessels, along the periosteum, proceeded in such a manner as to be quite sufficient to sustain the vitality of the parts.

Then another principle of treatment for these nævi, where you do not like to extirpate them, or the application of the ligature may be impracticable (for sometimes the figure and situation of the nævus are such that a ligature cannot be applied), consists in a kind of attempt to imitate the process of natural cure, which I mentioned consists in an accession of inflammation and ulceration, sometimes leading to partial sloughing of the tumor. It is the application of caustic to the tumor. Mr. Wardrop recommends an application to the centre of the tumor of a portion of potass, or rubbing the tumor thoroughly with the nitrate of silver; but the potass is the most effectual. He says it will produce a certain degree of inflammation at one part of the tumor, like the natural process, and that this will diffuse itself over the whole of the texture; and thus you will get rid of a nævus which is too large to attack with the knife. Not long ago he sent me a patient to look at, with a large nævus on the neck, which he thought too large to admit of being treated by excision or ligature. He applied caustic in the way that I have mentioned. The cure is going on favourably; and he has employed it to another, which is also going on well. At all events you know from this that the caustic may be safely employed in cases of this nature.

Another method lately proposed, and which in some instances has been adopted with great success, is that of vaccination on the nævus, in children who have not previously been the subject of the vaccine disease. You introduce the vaccine matter at points all over the nævus, and round it, so as to produce a considerable degree of inflammation in the textures. I have tried this in two or three instances: in one case with complete success—in one case with partial success; and I have seen an instance lately where it has entirely failed, although the nævus was not large, and I was obliged to extirpate it. It was seated on the scalp.

ANALYSES & NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégé.”—D'ALEMBERT.

FEVER.—ART I.

A Treatise on Fever. By SOUTHWOOD SMITH, M.D. Physician to the London Fever Hospital. London, 1830. Longman and Co.

Clinical Illustrations of Fever; com-

prising a Report of the Cases treated at the London Fever Hospital, 1828, 1829. By ALEXANDER TWEEDIE, M.D. Member of the Royal College of Physicians of London, Physician to the Fever Hospital, &c. &c. London, 1830. Whittaker and Co.

WHEN we took up Dr. Smith's work, for the purpose of critical analysis, and read the comprehensive title, “A Treatise on Fever,” we would willingly have retired from the task, as from a laborious undertaking which promised but little reward; but in glancing through the book, we found the author had treated only of the epidemic, or common continued fever of this country, which, although sufficiently extensive as a subject in itself, is nevertheless more within our grasp. Works on fever do not in general excite great interest—the regard they meet with is of a passing and transitory nature, and yet, in the face of so great discouragement, there have not been wanting, at every period, zealous and able men, who have stood forward in the cause of science, sacrificing their time, their health, their life, in the investigation and contemplation of this scourge of the human race—fever.

If there was wanting testimony to shew the foremost place which fever holds in the science of medicine, it would be found in the long list of celebrated men of modern times who have bestowed upon it their particular attention, as well as in the train of great characters who have lived through all antiquity. Nothing but a conviction of the necessity of a knowledge of fever, as the groundwork whereon to erect a stable fabric of the science of medicine, could have enlisted so much talent and commanded so much labour, which, although not yet repaid by the successful attainment of the desired object, has nevertheless drawn together a mass of evidence that will ensure the respect and facilitate the researches of all future inquirers.

We are not of those who view the subject of fever with despair, or who think the time far distant when the doubts and difficulties in which it is involved will be cleared up and overcome. Much is already accomplished, and we look forward with confidence to the philosophic spirit and persevering industry of the present age to perfect the great remaining work. Hitherto a knowledge

of fever has been attainable only in part, because, from our defective acquaintance with morbid anatomy, we have not been able to trace its phenomena to their proper source, or to separate those conditions which supervene and are accidental from those which are essential and original. This great work of analysis, based on morbid anatomy, and conducted with a method of reasoning bordering on mathematical precision, is advancing successfully, and promises to substitute a sound pathology in place of vague conjecture.

The great doctrinal errors which have from time to time prevailed in medicine, owed their birth either to the reasonings of great minds on an incomplete series of facts, or to the extravagant speculations of a wild and ardent imagination; and these errors have obtained, in proportion as we have been ignorant of the structure and functions of the body in health and in disease; but as our knowledge of these particulars is improved, so will false theories be dispersed, so will there be furnished correct data for legitimate induction, in accordance with the Baconian principles of philosophy; and in no respect will these principles, we sincerely believe, enable rational medicine to achieve a greater triumph than in establishing the exact rank and relation of the phenomena of fever.

The Treatise first on our list is limited (if we except a few remarks on scarlet fever) to an account of the common continued fever of this country, and is divided into nine chapters. The author's object "is to ascertain the real phenomena of fever, and the most safe and effectual treatment of the disease;" as well as to carry into effect two important purposes in the establishment of the London Fever Hospital—namely, the accumulation of facts and the cautious trial of remedies. The author first gives a short account of the Fever Hospital, and of the ancient and modern doctrines of the nature and seat of fever. Then follow observations on the varieties and phenomena of fever, on the importance of analysis, on the organs and functions always deranged and diseased, on the distinction between fever and inflammation, and on the relation between the plague, yellow fever, &c., and the varieties of the fever of our own country; all which the author considers as varieties produced by dif-

ferent intensities of the same affection. Cullen's classification of fevers is handled with petulance and severity, and afterwards adopted. Synochus and Typhus are divided into mitior and gravior; and of these a further very questionable and perplexing division is added, according to the different organs in which the several affections have their seat. Hence synochus gravior with cerebral affection, subacute and acute; with thoracic affection, with abdominal affection, with mixed affection; and so also with typhus. The chapter winds up with a fierce struggle to prove the absurdity of the notion of debility, with which the author is sadly out of humour, and which he has taken great pains to keep out of view. To this succeed some remarks on scarlet fever; after which the author treats of the pathology of fever, and introduces an unnecessary number of imperfectly detailed cases in illustration. Next comes a chapter on the theory of the disease, in which there is much labour for originality, as, indeed, is conspicuous throughout the work. The causes of fever occupy the eighth chapter, and the last is devoted to treatment.

Our analysis of the two works placed at the head of this article will be separate, as we are desirous of paying an equal respect to both the authors, and more extensive than is our general custom, because we feel it our duty to give a full consideration to the works of physicians who have such an opportunity of studying fever. How far this opportunity has enabled them to add to our knowledge of fever, we shall by-and-by consider; but we may remark, *en passant*, that the novelty is rather in manner than in matter. Indeed the work of Dr. Smith is a very curious composition, and appears to us to be a close, though a studiously varied, imitation of a master whom he does not acknowledge. To this subject we shall frequently have occasion to return, in the progress of our analysis. Before we proceed, we must pause a moment at the title; which, with submission, we take leave to say is not appropriate to the contents. The generic term fever comprehends many varieties; Dr. Smith's work embraces only one—thus falling into a common but a fundamental error; and we scarcely need remark that this incongruity is not consistent with clear and comprehensive views.

As is too common, our author commences by drawing a dismal picture of the present state of our knowledge of the disease he is about to describe; and this opens a spacious field for a kind of display which we cannot but regret, disapproving of it as we must do in justice to those, his predecessors, whose labours deserve our approbation. After declaring our ignorance of the origin and propagation of fever, the difficulty of discriminating what are the essential symptoms, and what the adventitious, he says, "when we consider how few comparatively of the external appearances have been ascertained to be the sure and certain signs of any known condition of the internal organs, and how often the existence of several known conditions of the organs remains altogether unsuspected until the demonstration of it is afforded by inspection after death; and when, finally, on all these accounts we consider how vague the objects must be that are aimed at in the treatment; and consequently how uncertain, how indiscriminate, how fruitlessly inert, how perniciously active, how unsuccessful, how fatal, that treatment often is," &c. p. 2; it was not without surprise we perused the above, because we have at hand authority from which to adduce "sure and certain signs;" and it was not without regret that we found the remarks too well borne out by the author's cases, in which much unsuspected organic disease was found on dissection, as well as by his recommendation of a treatment which we cannot but believe "perniciously active."

Dr. Smith next glances at the notions of Hippocrates, Galen, and Sydenham, on the nature and seat of fever; and then, under "modern doctrines," gives a short abstract of the opinions of Cullen and Brown, as a prelude to those of Stoker, Burne, Clanny, Clutterbuck, and Broussais. It is an easy, though not a generous triumph, for men of the present day to expose the fallacy of doctrines formed in the infancy of science. Even great minds can reason only on what they know; and if we place before ourselves a correct picture of the data on which his reasonings were grounded, we shall find the opinions of Hippocrates less deserving of censure than those of some celebrated men of our own times. The quotation of Cullen's hypothesis of spasm, does

not appear to us apposite on the present occasion, referring, as it does, expressly to the proximate cause of the febrile paroxysm; a point which Dr. Smith does not take up, and which is in no way allied to doctrines of the seat and nature of fever.

The opinions of Stoker, Burne, and Clanny, are, as our readers know, in favour of the common continued fever being a general disease, in which the chief feature is a depression of all the powers of the body; while the opinions of Clutterbuck and Broussais are in favour of this fever being a local inflammatory disease. In commenting on these opinions, our author remarks—"As must necessarily be the case, these different and opposite theories are found to have the most important influence on the practice recommended by their respective authors in the treatment of the disease. The advocates of the first, deprecate all active interference; the grand evil to be contended with is debility. The physician can easily weaken, but he cannot strengthen; he can depress to any extent he desires, but he cannot communicate power as he wishes. In a malady, therefore, of which the very essence consists in loss of energy, the main duty of the physician is to husband the strength of the patient with the most anxious care; this being the chief means, as Cullen expressly termed it, of obviating the tendency to death. The important *inference* is, that every kind and every degree of depletion that can add to the primary cause of the malady, must be abstained from with the utmost caution. By the clearest and shortest deduction, this will necessarily be the result to which every mind must come that really believes that debility is the essence of fever, while he who admits its inflammatory nature must think it criminal to stand idle by, and allow the most extensive derangements in the structure of vital organs to proceed, without even an attempt to check them, as long as it is his in his power to use the lancet or to procure leeches." p. 27.

This extract offers one of the examples which we have already alluded to, of the exaggerated picture which Dr. S. draws of the opinions of others. Instead of giving an exact statement of the treatment recommended by the authors quoted, he *infers* that every kind and every degree of depletion must

be abstained from on the one hand, and on the other he *deduces* that blood must be abstracted as long as there is power to use the lancet or to procure leeches. Verily we are at a loss to know in what parts of the works of Stoker and Burne, or Clutterbuck and Broussais, the author will find his inference and deduction borne out; and we lament to see him allow his imagination thus to run riot. An advocate, or the writer of a romance, may give a colouring to his representations, but science demands exactness.

In the second chapter are discussed the definitions of fever, as given by nosologists, to all of which objections are made. The author speaks of Boerhaave's laborious analysis of the symptoms of fever, by which he reduced them to three—"shivering, frequent pulse, heat." To these Cullen makes the following additions—"languor, lassitude, and other signs of debility, together with derangement of the functions, particularly a want of vigour in the limbs, without any primary local affection."—"This extension of the catalogue (says our author) adds in no respect to the excellence of the generalization. It has all the vices which a definition can possess," p. 45. Here, again, Dr. S. treads in the steps of his unacknowledged master, imitating him in his abuse of Cullen; indeed the imitation is so close in every point, that there is scarcely a page in the work in which some opinion or expression does not bring Dr. Armstrong to our mind, although his name is so studiously kept back.

Now it is an injustice to so great a man as Cullen to suppose that he would run into blunders as palpable as Dr. S. would make them appear. The name of Cullen should, at any rate, be mentioned respectfully by our author, particularly when his own work may possibly afford as many examples of "vice" and inconsistency as are to be found in Cullen.

Before authors discuss a definition of fever, it should be settled what is meant by the term. Does it mean any given state; or any given disease; or any given stage of a disease?—because the definition must vary accordingly. If it means a given state, then there can be no difficulty; as it would be only to enumerate the symptoms of that state—as heat, accelerated pulse, with derangement of the functions; which is

a state of fever, occur in what disease it may. But if it means any given disease, as the common continued fever, then we ask who can give a definition applicable to all the states of this universal affection? The thing is not possible; and it is to view Cullen's definition unfairly, to suppose that this was intended. It is, then, idle to adduce states in which all the symptoms in Cullen's definition are not to be found; and will Dr. Smith, still wielding the weapons of his unacknowledged master, presume to say of Cullen, that assemblages of symptoms enumerated by him "do not even exist in nature?" The Doctor must have seen, if prejudice would allow him, the very states and assemblages of symptoms quoted from Cullen; he must have seen fever having a very different aspect at the beginning and at the end—having an inflammatory character at the outset, and at the end a typhoid. Has he not seen exquisite examples in the fever of small-pox? We remember Dr. Armstrong, when ridiculing Cullen to his wonder-stricken class, comment severely on Cullen's definition of synochus—"initio synocha, progressu et versus finem, typhus," he exclaimed exultingly, that if this synochus was one thing at the beginning and another at the end, what was it in the middle? This was pitiful.

The series of events, or in other words the order of the symptoms, are much insisted on, and bring our author to the conclusion that there is, first, derangement in the nervous and sensorial functions; secondly, in the circulating functions; thirdly, in the secreting and excreting functions: this is the last result in the succession of morbid changes.

The third chapter opens by a description of the synochus mitior, which is drawn chiefly from the author's own case, "he having suffered a severe attack of fever." This description is well written, and in an appendix would be interesting, containing, as it does, the feelings and workings of the mind under the attack; but it is ill calculated for a graphic account of an attack of fever; being much diluted, and its chief features scattered through many pages instead of being comprised in one; it is moreover very defective in the characteristic physiognomy of fever. "The colour of the face (he says) is pallid; and the general aspect is so peculiar

that an experienced eye can distinguish the disease," &c. Authors should write for the inexperienced. No condition gives such a field for description as the face of a person labouring under the common continued fever; but this Dr. Smith has omitted very unaccountably; though we guess this detail has been passed over, lest it should shew signs of debility, which is not the author's object. He says nothing of the general dull and dusky (not pallid) skin, the depending eyelids, the dull pearly eye, the vacant countenance, the half-open mouth, and all the other effects of muscular prostration.

A description should be concise to convey a striking picture to the reader, and it must be drawn from the patient, not from the sick physician himself, for the depressed mental energy of one afflicted, or about to be afflicted, with the common continued fever, is a barrier to correct and acute perception. The first sign which our author felt when sickening, was a loss of mental energy, and this he experienced for a considerable time before he was conscious of any corporeal debility. This mental depression may have blunted his consciousness, for corporeal debility is one of the earliest signs of an attack of fever: patients feel dull and weak, and know not why; they sit and lie all the day, and if they move about, their knees are ready to give way under them; the muscles can scarcely hold the bony frame firm enough together to support the weight of the body. Now we beg to ask Dr. S. as a physiologist, can there exist this depression of mental energy without a corresponding depression of muscular energy? Is this depression confined to the intellectual faculties, or does it affect the whole nervous system and the muscular as a consequence? Undoubtedly it does; it cannot be otherwise. But then this would be to admit signs of debility!

Our author's notions of the difference between the mild and severe forms of fever are, that the difference is the consequence of the addition or supervention of inflammation in certain organs, on which account he ranks all the inflammatory affections with the synochus gravior, and thus he speaks of synochus gravior with subacute and acute cerebral affection, with thoracic affection, with abdominal affection. There is no mention of inflammation as connected

with the synochus mitior. In our humble opinion this view embraces a radical error: it is not the organic inflammation that modifies the character of the fever, for the fever may be of a mild form, as regards its peculiar character, though the inflammation may be subacute or intense; so may the fever be of a severe form, whatever be the degree of inflammation. It is the inflammation that is modified by the fever, not the fever by the inflammation. Thus the synochus mitior may be complicated with every variety of inflammation, as also may be the synochus gravior. It is very important to know how the common continued fever and inflammation are acted upon by each other: we agree with our author that the inflammation is modified by the fever, but not that the character of the fever is modified by the inflammation. The erroneous notion above spoken of, renders the author's account of the synochus gravior with subacute and acute cerebral affection, not very intelligible. Now the acute observation of Dr. Armstrong soon discovered to him that inflammation frequently existed in cases of fever, and he, without waiting to analyze this complication and to find out the relation in which the fever and the inflammation stood to each other, at once and hastily made this complication one of his divisions of typhus, and called it "inflammatory typhus." Dr. Smith's divisions are little more than a version of Armstrong's, and he has even borrowed his expression of fever *passing* into inflammation; which, by-the-by, is not intelligible, nor, with submission, do we think possible; it was evidently meant by Armstrong to point out the important fact, that organic inflammation is often an adjunct to fever. On this subject a recent author, Dr. Burne, is more explicit, he regarding inflammation as accompanying the different types of fever; and as his remarks are short, we subjoin them in a note*.

* "At whatever time, or in whatever way the inflammation may arise, it is modified by the adynamic fever; for the prostrate condition of the nervous and muscular systems, which has been described as pathognomonic of this fever, prevents the inflammation going on with full force; it gives to the inflammation a character which is known by the term atonic; and the inflammation partakes of this character, more or less, according to the degree of the adynamic fever, the adynamic state having a direct tendency to depress the violence of the inflammation."—Page 41.

"The degree of local inflammation is by no

The synochus gravior with subacute cerebral affection is, we are informed, the same in its access and progress up to a certain period, when the pain in the head, instead of diminishing, increases; still the pain is not severe: this account does not tally with our experience. Several pages are occupied in discussing the indications of pain and giddiness, and in attempts to erect a diagnosis upon these signs,—but here we do not comprehend our author; indeed, his own views are evidently not exact and clear. The synochus gravior with acute cerebral affection, in the most acute form, is precisely the same as the subacute, except that the symptoms are more severe, and their progress quicker. The head-ache is much more intense, and this leads the Dr. to the extraordinary case of the apothecary of the hospital, Dr. Dill, which, however, we will not mangle in this place, but reserve it to be spoken of under the treatment. We have not been accustomed to see “intense” and “ferocious” head-aches in fever, nor has inflammation stared us in the face as it has done our author.

All the signs of the acute cerebral affection, noted by Dr. S., have not appeared to us to depend so much on vascular as on nervous excitement: the difference between these two affections does not seem to have struck our author; his creed is inflammation, nothing but inflammation—and his practice bleeding, nothing but bleeding: but as he grows older, we trust he will learn to distinguish the mockery of a nervous excitement from the reality of an inflammation.

In illustration of the subacute and acute cerebral affections, are five cases, which, with submission, we think are unfortunately chosen, being ill adapted to support the position—inflammation; indeed the Dr. shrewdly guesses as much, for in the introduction to the last case he says, “if the reader can

means necessarily commensurate with the degree of the adynamic fever. The degree of inflammation may be violent, while the degree of the adynamic character of the fever is slight; or the degree of inflammation may be slight, while the degree of the adynamic character of the fever is severe; or the degree of the inflammation and of the adynamic fever may be simultaneously slight. Thus the adynamic fever of the first degree may be attended with a severe pneumonia; or the adynamic fever of the third degree may be attended with a slight pneumonia.” Page 43.—*A Practical Treatise on the Adynamic or Typhus Fever*, by John Burne, M.D. &c.

doubt of the condition of the brain in this case, he is requested to turn to the pathology,” which is anticipating the reader’s doubt as to the first four. And respecting this fifth and last case, we have been rather embarrassed to find the dissection in the pathology, the case being there numbered differently, and again reported in a more concise form: in one account the patient is said to be 36 years of age, in the other 26, but the accounts accord in so many other particulars as to leave no doubt of their identity. The first case is in our judgment merely an example of the synochus mitior: no treatment is given. In the second case, there was headache, but we do not remark any sign of inflammation, unless this was the index, which of itself is an insufficient one. In the third case, we should attribute the head symptoms to the state of the abdomen; and the indistinctness of mind would probably have been relieved by freeing the alimentary canal of its foul contents, as we have often witnessed; for although there may be a loose state of the bowels, there is often foul and filthy matter retained, which is the case especially in the second stage of fever. This case recovered after a very slow and tedious convalescence; but we are not put in possession of the treatment even here. In the fourth case, the bowels were constipated and the abdomen tender, which would aggravate the head-ache of fever: the patient was cupped to xxviii. and next day was reported “more sensible since the cupping,” but no mention is made of the alimentary canal, whether the aperients had operated, or what the nature of the stools; nor do we find more mention of the bowels till after *three* days, when the urine and dejections are passed in bed, shewing excessive prostration. The patient ultimately became salivated, but did not leave the hospital until the *sixtieth* day from the attack, having been admitted on the *eleventh*: we ascribe much of this protracted convalescence to the loss of blood. We cannot even meet our author’s views in the fifth and last case, on which he mainly relies for the conviction of his readers. It was not admitted till the fourteenth day of the disease; and we are at a loss to discover any thing in the history, or in the dissection, to call for or even warrant the abstraction of so much blood at a late period. The pain

in the head is gone one day, but returns the next; it goes again in like manner, and again returns: we know of no inflammation of the brain of any degree or kind soever, in which there is this entire absence or removal for a time: pain in the head in fever may be removed by bloodletting, but it returns, and he who, like our author, returns to the attack with the lancet, will too often reduce the vital powers to a point from which they rally no more; as was the case in the instance before us. The patient died on the 29th day; and on dissection, there were found three ounces of serum in the ventricles: but the brain and membranes were pretty healthy, except some coagulable lymph (consistent albumen?) on the tuber annulare.

Now we would ask, what was the state of the urinary organs here three days before death, when there came on extreme restlessness, almost constant moaning, and the pulse rose suddenly from 75 to 120? we suspect there was ammoniacal urine formed by retention in the bladder, which gave rise to the symptoms above-mentioned, as also to the ventricular effusion. We have very lately witnessed a similar case. Extensive lesion was also found in the liver and lungs, enough of itself to turn the balance against the patient, even without the loss of blood; and with it, destruction was certain. Knowing how ill patients bear the loss of blood who have organic lesions, and how surely destructive free bloodletting is in cases of fever attended with these circumstances, we can scarcely believe our senses when we read in Dr. Smith's comments on this case, his regret that more blood was not taken away on the 15th and 16th days. This poor creature, admitted as late as the 14th day of her fever, and affected, as the dissection proved, with a hard liver, and having also the pleuræ adherent, and *the substance of the lungs full of tubercles in different stages of the disease, (viz. in a confirmed phthisis, we suppose,)* is considered to labour under an acute cerebral affection, for which 32 oz. of blood are drawn at different times, and in addition, eight leeches applied to the head; and yet our author regrets that more blood was not taken. Can any thing equal this infatuation? What patient having the substance of the lungs

full of tubercles, in different stages of disease, can stand up against the merciless lancet? No mention is made of medicine—no remedy noticed but bloodletting, shewing the exclusive prepossession of the author's mind.

Synochus gravior with thoracic affection.—Our author is of opinion, that the mucous membrane of the bronchi is not in a perfectly sound state in any case of fever, and that a certain affection of it is peculiar to this fever; but he enters into no detail of the nature of this affection, though he adduces a train of symptoms which may be contrived to refer to any disease whatever of the chest. These examples are subjoined in illustration, which we will notice when we come to the chief body of cases.

Synochus gravior with abdominal affection.—"One of the organs," says Dr. Smith, "always involved in disease in a greater or less degree in fever, is the mucous membrane of the stomach and bowels," and although in slight cases it produces no change of structure, he believes it is really diseased even in the mildest cases. "Abdominal affection exists under two forms in fever, each of which is attended with distinct and peculiar symptoms." The first form appears to us, from the description, to be a simple gastritis, or a cholera, or a dysentery, the symptoms being nausea, retching, vomiting, and purging, with pain; but these we cannot consider as belonging to fever. We have seen a vast number of these cases in the last autumn, but had no reason to ally them to fever; they do not form a part of the disease like the second affection, the disease of the ileum. These are accidental complaints which may or may not be attended with the common continued fever; and moreover, they are quickly relieved, and in the majority there is only a sympathetic febrile movement, which vanishes as soon as the gastric irritation is allayed. In this abdominal affection, our author follows Armstrong most closely.

The second form of abdominal affection "is attended with much less striking symptoms," and requires great attention to discover its presence and trace its progress—it steals along its fatal course, and is often "unfelt by its victim, and undiscovered by his most watchful guardian." Though we consider even the most latent abdo-

minal affection for the most part to be distinctly marked by external signs, we sincerely concur in the observations of Dr. Smith, that the intestinal affection is very imperfectly understood, generally speaking, and consequently very inefficiently treated; for often have we seen the temples leeches, and other remedies directed to the head, when all the symptoms depended upon the intestinal canal. It is our belief, that after the tumult and commotion of the first days of fever have passed by, the disease is often wholly kept up by the disordered condition of the intestinal canal; and it is to an improvement in the treatment of this particular affection that we have to look for the power of rendering the course of fever shorter, diminishing it from weeks almost to days. Of this abdominal affection, the Dr. enumerates but few symptoms, as tenderness on pressure, which, he says, is sometimes wanting; looseness of the bowels, which, he says, may or may not exist, or there may even be constipation; while the tongue is generally red at the edges and tip, loaded with dirty grey or yellow fur, and sometimes dry, the pulse being generally 120. Now there is here no mark by which to know the presence of disease; for every sign mentioned may or may not be present according to our author; as there may or may not be tenderness on pressure, there may or may not be a loose state of bowels—there may or may not be a dry tongue. Here the Dr. fails in the analysis of the symptoms, as we think he does on other occasions: he mentions a train of symptoms which occur, no doubt, and which he has witnessed, but he does not analyze them, and refer the separate assemblages of signs to the particular states which they represent, and therefore the reader is lost; for it is clear that what an author does not know precisely, he cannot with precision communicate. These remarks apply also to the little work of Dr. Bateman, which, whatever may be its other recommendations, is but of little value as a clinical guide. We could readily dilate on the affection of the intestinal canal, and enumerate the signs which indicate its peculiar condition, and the circumstances which attend its development, but this would be to write an essay, which is not our business: we may, however, close this

part of the subject by expressing our surprise that the flushings of the face, the nature of the dejections, and the meteorizations, should have almost escaped our author's attention.

Synochus gravior with mixed affection.—Here two or three of the affections above-mentioned exist simultaneously, as the cerebral with the thoracic, or with the abdominal, or all together, and are indicated by their particular signs.

Next follow typhus, with cerebral, thoracic, and abdominal affections, as in synochus. As these depend, says our author, on difference of intensity, it is unnecessary to go into them, particularly as we find no satisfactory diagnostic marks. Here our author is compelled to admit there is prostration, and in so doing he, unawares, acknowledges there is prostration in synochus, which before he had denied. He observes, "there can be no doubt, that from the very first commencement of the attack, as well as through the whole course of the disease, the prostration of strength, both physical and mental, is greater than it is in synochus;" and yet a few pages further on, when speaking of typhus gravior, he says, "they (the intense forms of the disease) have been conceived, (by whom we beg to ask?) to form exquisite specimens of diseases of debility;"—"but where is the debility?—Not in the disease, for that is of giant strength; not in the patient; for remove, if you can remove (ay, there's the rub) a part of the load that oppresses him, and instantly an intensity of action will set up in the whole system," &c. p. 164. These extracts exhibit a sad contradiction; but truth will out. The author allows his imagination to run on before his judgment, as is seen in the last extract; and when any fine turn of language crosses his mind, he cannot resist the temptation to introduce it, however inappropriately, as in the exclamation, "where is the debility?" and in the reply, "not in the disease;" although this answer is at variance with what was advanced a few pages before. This is what Bacon would call an attempt "to suppress truth by the force of eloquence and speech." One would suppose the Doctor was spouting to an assembly; for in a popular harangue, the hearers, like the orator, may be carried away by a redun-

dancy of plausible and figurative language; but in a book of science, gravely laid before the public, these things are weighed in the balance, and woe betide the author if they be found wanting.

Passing over a short chapter on scarlet fever, we shall proceed in another article to a very important subject—the Pathology of Fever.

Remarks on Nervous and Mental Disorder, with especial reference to Recent Investigations on the subject of Insanity. By DAVID UWINS, M.D.

BEFORE making any allusion to the work whose title has been quoted, we take this opportunity to settle a certain little account with the learned and facetious author. We have not forgotten—nor has Dr. Uwins, that our opening number contained a notice of his work on Indigestion. This notice, we maintain, notwithstanding all that he has said of it, and after all the time which has elapsed since it was written, to have been a fair review; keen, it is true, but still “within the limits of becoming mirth,” *i. e.* reviewer’s mirth. There was in it nothing personal nor coarse, and we had fancied that even the victim of our critical dexterity would have been gratified by the epigrammatic point of the article. But little did we anticipate the storm which was brewing. Month after month passed on, and we continued our undeviating and upright career, the good opinion of surrounding persons seeming to “grow with our growth, and strengthen with our strength,” when about the period of our second anniversary we beheld a new-born candidate for the support of the literary and professional public. We hailed the appearance of the “Medical Examiner” with that subdued and doubtful welcome which attends the arrival of one who is expected to deprive another of some part of his possessions: we own that on finding Dr. Uwins—as if in anticipation of the speedy descent of the publication to “the tomb of all the Capulets”—busily employed in paying his debts to contemporary journals, “right and left:” we read on right willing to see fair play; for, as La Rochefoucault says, “there is something in the misfortunes of our best friends which is not altogether displeasing to us;” but we were in the

end a little startled on discovering that all this was but mere playfulness compared with a tremendous attack upon ourselves. We ended the climax in a long series of sufferers under the Doctor’s lash, and were certainly “scourged with scorpions.”

We have now an opportunity of revenging ourselves; for Dr. Uwins, in his last *brochure*, has, in our judgment, wilfully laid himself open to criticism. So palpable, indeed, are its faults, that we should make ourselves ridiculous by noticing them seriously.

Most unluckily for our author, the late Mr. Gifford, in an evil hour, accepted an article on Insanity from his pen; it appeared in the “Quarterly,” and this event seems to have been too much for the worthy Doctor, who, we verily believe, has never written any thing since that time without alluding to it. Even in the pamphlet before us, we are once more told of the “success of the article”—of the “praises” bestowed on it “by those whose praises were highly to be appreciated,” till at length the author, *maugre* all an author’s fondness, seems to be ashamed of the reiteration; for, in his concluding reference, he very truly calls it the paper, “in alluding to which I fear I sicken my reader,” &c. After fourteen pages of preliminary matter, in which he likens his predilection for insanity to Dugald Stewart’s preference for metaphysical investigation, Playfair’s for natural philosophy, and that of Lawrence, Turner, and Wilkie, for painting, we come at length to the gist of the argument, which is to shew, 1st, that mental and mere nervous or “sentient” disorders are too much separated; 2d, that medical men are better acquainted with these than *lay* practitioners; and 3d, that Lunatic Asylums, if called by any other name, “may be of essential service to the community,” and ought not to be viewed with sentiments of hostility any more than houses of recovery from fever, &c.

The two last come so nearly under the description of self-evident truths, that we shall not stop to illustrate them. The first affords more field for discussion, and we shall give a specimen of our author’s mode of handling it;—having first taken occasion to deprecate the idea of there being any thing like hostility in the “lively sally” which may now and then escape the pen of a con-

troversialist. Having premised this, we may state that Dr. Uwins is physician to the Peckham Asylum, and that the manner in which he commences his endeavour to prove his first position is by informing us, that one of the first patients he sent there did not labour under insanity. We shall give his own words:—

“In defending the first of the above positions, I shall commence with a startling announcement. It is this—that almost the first patient I sent to Peckham Asylum was not mad. Indeed! exclaims my reader: then have at him, ye advocates of justice and defenders of law; surely this man, with such a confession from his lips or pen, deserves, if any one does, to be arrested in his career of inhumanity, and swept down by the *broom* of forensic authority. But stay a little, my gentle and generous critic; I will not give way so readily as some of my brethren have done, to the taunting power of froward contumely, but before condemnation will demand to be heard and attended to. What, however, I have further to say, in reference to the particulars of this case, I reserve for my third division: in the meantime, I invite my good friends, the barristers, to open with me a volume written by one Shakspeare, ‘a name that always recalls to his intelligent readers the first of poets, and the most penetrating of observers’—a man who had ever the power of truth at his call, and the pen of nature in his hand. Now, although I once heard a medical man inquire who was the author of Beaumont and Fletcher; and although it was told me of another, that he remarked upon a glorious passage from our immortal bard, ‘Yes, it is very pretty;’ and although there may have been *even among us* an occasional manifestation of moral turpitude, to the extent of saying any thing, however false, for the sake of lucre; and although you gentlemen, who are the professed advocates of—truth, have recently not evinced any very extraordinary respect for the professors of a rival art, yet you will, I hope, allow that there is at least literature and discernment among us sufficient to appreciate the force and truth of the great master whom I am now to quote; and were it not that I should thereby give you some latitude for the exercise of your contumely and scorn,

I would go further, and say, that there is more to be found in the volumes of Shakspeare, on the head of mental disorder, its circumstance and philosophy, than in many of our medical authors who have written on insanity.”

We have then some further commonplace remarks about Shakspeare, after which the discourse falls upon Le Sage, and the connexion between nervous and mental disorder is illustrated by the well-known story of the Archbishop and his Secretary:—

“The eloquent prelate to whom Gil Blas was appointed secretary, fell, it will be recollected, into apoplexy; he recovered, however, from it so far as to be able to compose and deliver homilies; but lo! these productions, instead of being now marked by the features of legitimate and impressive eloquence, are turgid, and bombastical, and inane; while the preacher still imagines them beautiful and good.”

Dr. Uwins, we believe, never had a fit of apoplexy. After a few more “lively sallies” of this nature, the author at length assumes a graver tone. This part he begins with—“To be serious,” and it is the first sentence in the pamphlet which provokes a smile. But “serious” with the Doctor we cannot be without differing from him, and we prefer on this occasion expressing to the author our willingness to understand, in his own way, all that he says, and to be on as good terms with him as he seems to be with Dr. Uwins, provided he will for the future consider that all his readers may not be equally able, nor equally willing, to penetrate his design, and humour it; and provided he will bear in mind that “no author was ever written down but by himself.”

CASE OF SUBCLAVIAN ANEURISM, WITH OBSERVATIONS.

To the Editor of the London Medical Gazette.

SIR,

THOMAS BRIGGS, aged 54, by trade an iron-plate worker, was admitted into St. Bartholomew's Hospital on the 25th March with a pulsating tumor, situated immediately below the left clavicle. He

stated that it had been gradually increasing for about ten months. On a careful examination, there was reason to suspect that the tumor was caused by an aneurism of the subclavian artery at the part where it passes beneath the clavicle. The tumor was of the size of one half of a large orange. The lower margin of the tumor was firm, and no pulsation could be felt at this part, nor when examined from the axilla beneath the edge of the pectoral muscle: at the upper part the tumor was softer, and pulsation was very distinct. No additional evidence was afforded by an examination with the stethoscope. The pulsation in the humeral and radial artery *was as strong as on the healthy side*. This circumstance, added to the firmness of the greater part of the tumor, induced me to entertain hopes that a spontaneous cure, by obliteration of the aneurismal pouch, might be effected without the current of blood in the direct course of the artery being arrested. On looking to Mr. Hodgson's and other practical works for information on this subject, I could not find any recorded instance of such an occurrence in a vessel of this order, although there exist many dissections proving the possibility of such a termination in vessels of a larger calibre, and in some cases of spurious aneurism from punctures of the artery at the bend of the elbow. Entertaining this view of the subject, I was induced to delay performing the operation, which would have been doubly hazardous in the very deranged state of the patient's health, who suffered much from pain in the region of the stomach and liver, accompanied with frequent vomiting. His complexion was very sallow, his skin bedewed with a clammy sweat, and his tongue was much coated, and morbidly red at the tip. All these circumstances combined warranted the delay which took place, the tumor being accurately measured from day to day with a gauge made of pasteboard. The treatment pursued consisted in repeated moderate bleedings from the arm; the frequent application of leeches to the pit of the stomach, from which he derived marked alleviation of pain; very low diet; and saline medicines. He took also for two days the tincture of digitalis, but this disordered his stomach so much that it was discontinued.

As he complained of heat and pain in

the tumor, extending down the arm, he was directed to keep pounded ice in a bladder upon the tumor. From this he derived great relief, and although it was applied night and day, the integuments did not suffer. Under this treatment his general health improved, the tenderness of the stomach diminished, and the tumor remained stationary as to size, and the pulsation became less distinct. The pulsation in the artery beyond the tumor remained free and undiminished. Such was the state of the case on Saturday the 10th of April, when I called a consultation with my colleagues to decide on the propriety of operating, or persevering in the attempt to favour spontaneous cure. I submitted to them all the circumstances of the case, and particularly directed their attention to the fact of the undiminished strength in the pulsation of the artery beyond the tumor, which I was led to consider as favourable to the supposition of the pouch occupying only one side of the artery, and consequently receiving but a slight impulse from the circulation, whilst the bulk of the circulating blood passed on in a direct course to the artery below. My argument was founded on having repeatedly observed that the circulation in an artery below an aneurismal sac was much more feeble than in the opposite healthy limb, and on the belief that if a certain portion of the vis a tergo was expended in transitu through the sac, the force in the circulation beyond it must necessarily be diminished. The prevailing opinion was, however, opposed to this, and the very circumstance of the force of the circulation below was considered as proving the free ingress of blood into the sac, and consequently the slight probability of any spontaneous cure. It was further urged that there were no recorded instances of obliteration of the pouch without impeding the flow of blood through the artery in a vessel of the order of the subclavian. The patient was now in a more favourable state for operation than when he was admitted, and it was possible that by a further delay the tumor might increase, and the clavicle be more raised, which would increase the difficulty of the operation. Of this latter circumstance I was fully aware, and, as I had no facts to adduce in support of my argument, I yielded to the opinion of the majority, and resolved to perform the operation

without further delay. Up to this time the patient had been kept in ignorance of the probability of any operation being necessary, from my wish to keep his mind and body in that state of tranquillity so essential to promote the efforts of nature. A gentleman incautiously mentioned the operation within his hearing, without any preparation, which excited him greatly, and he rose from his bed in great agitation, and could with difficulty be restrained from quitting the house. I explained the nature of the operation to him, and the necessity for performing it, and gradually tranquillized him; but he was not in a fit state to undergo the operation on that day.

On examining the tumor on the 13th it appeared to me that it was increasing in a direction beneath the clavicle, although the gauge showed a slight diminution in the more prominent part below. The following day was consequently fixed on for the operation, which was performed in the following manner:—The patient was placed on a table, with the head and shoulders slightly elevated. An incision was made through the integuments and platysma myoides, about four inches and a half in length, along the upper edge of the clavicle. It was necessary to divide a considerable vein which crossed the wound and entered the jugular: a ligature was passed round this, and the dissection was cautiously proceeded with, in doing which I was materially assisted by having a small knife shaped like a cornea knife, only so blunt as not to cut, although it separated the firm cellular tissue more easily and with less violence than an eyed probe or the handle of a scalpel, which are commonly employed for this purpose. On introducing my finger into the wound, I could distinctly feel the beating of the aneurismal tumor, which had raised the clavicle considerably from the first rib, although the shoulder was not much elevated.

Having felt the tubercle of the first rib and the edge of the scalenus, my fingers detected a pulsating cord in the situation of the artery, under which I passed an unarmed silver needle without any difficulty. On examining this cord under which I had passed the needle, I distinctly felt the pulsation as strong as before; but on compressing it on the needle, the pulse at the wrist was not arrested, and the man com-

plained of a pain at the inner side of his elbow. It became apparent that I had surrounded the ulnar nerve, and not the artery which was situated immediately below it, and communicated its pulsation to the nerve even through the needle which was interposed. Previously to withdrawing the needle, I armed it with a silk, and requested Mr. Stanley to draw the nerve gently upwards and outwards. By this expedient, with a little more dissection, I fairly exposed the naked artery, and readily passed the same needle round it; and on compressing it, the pulse at the wrist was immediately arrested. The needle was then armed with a silk ligature, and the artery was tied. One end of the ligature was left hanging from the wound, which was closed with adhesive plaster. At the time when the nerve was drawn aside, the patient complained of pain in the elbow, which soon ceased after the operation. The bulk of the tumor was very slightly diminished by pressure immediately after the operation, and the contents of the sac felt very firm. Very little bleeding took place during the operation, and the only difficulty arose from the depth of the artery and the very deceptive feel communicated to the finger through the nerve which was situated immediately over the artery. It was remarkable that the pulsation was less strong when the artery was quite denuded than when felt through the medium of the nerve. This shews the importance of proceeding with great caution in this operation, when the touch, and not the sight, must often guide us; as I felt quite confident that I had surrounded the artery in the first attempt to pass the needle, but was soon convinced of my error by failing to arrest the pulse at the wrist when the nervous trunk was gently compressed upon the needle. I employed an unarmed needle in this case, which I always prefer, from the greater facility with which it can be passed than when armed—the wet silk often affording a considerable *obstacle*, and deceiving the operator as to the degree of resistance he meets with in passing the needle.

The operation was performed at one o'clock; at two, he complained of pain and numbness in the whole arm, the temperature of which was gradually diminished down to the fingers, which felt very cold. The arm was enveloped

in soft flannel. At half-past three a very slight pulsation was felt at the wrist, which was lost on the slightest pressure. I visited him at 8 p.m. and found his face flushed, and he complained of pain in his head. His respiration was unembarrassed, and the pain in the elbow and arm was diminished. Twelve leeches were ordered to be applied to his temples, and the bleeding encouraged with warm flannels. The leeches afforded much relief, and he had some sleep during the night. The following morning there was some return of pain in the head and general excitement, which was relieved by purging with saline purgatives. He had some hours tranquil sleep; but on my visiting him at one p.m. the flushing of the countenance and forcible beating of the carotids determined me to take more blood from the head; accordingly the temporal artery was opened, and xxvj . of blood were taken away, which afforded him great relief. During the state of excitement he complained of great heat in the left arm, but the temperature, on examination, was not higher than that of the opposite limb. From this time he went on very favourably, until the following Monday, when I found him very ill. He had experienced a severe rigor, which was followed by much heat and fever. His pulse was strong and frequent, tongue very loaded, and countenance flushed; and he felt assured that he should die. He was bled to the extent of twenty ounces, and a full dose of calomel and opium given, and the strictest quiet enjoined. I now learnt the cause of this excitement from another patient, who had been operated on for a popliteal aneurism on the right side, having undergone a similar operation, under my care, five years before, for the same disease on the left side. He stated to me, that it was impossible for Briggs to do well, for the moment my back was turned he was cursing and swearing at the nurse and every person who came near him. He was a very thankless, morose fellow, and was perpetually exciting himself and quarrelling about trifles. He was much subdued by the bleeding and other remedies, and I took the opportunity to talk very seriously to him, and to represent to him the exact situation in which he was placed; that, literally speaking, his life hung by a thread, and that he might be sum-

moned to give an account of himself in a moment, if he gave way to such intemperate conduct. From this time he continued to go on more favourably. He was very low spirited, sullen, and silent, but nothing sinister occurred. The ligature came away in a bread poultice on the sixteenth day. Since that time the wound has slowly granulated, but it still discharges rather copiously, and his health is still much impaired. His pulse is regular, he has no embarrassment in breathing, and he takes his food with appetite; but he has a very unhealthy desponding appearance. I hope, in a few days, to be able to remove him into the country, which, I trust, will re-establish his health. I have delayed sending any account of the case until the present time, being anxious to report him quite convalescent. As, however, the operation may be considered to have been perfectly successful, I am unwilling to delay any longer communicating the case to the public, more particularly as this is the first instance in which this artery has been successfully tied in St. Bartholomew's. Should any circumstances of importance in the future progress of the case occur, I shall not fail to communicate them through your valuable journal, and have the honour to be,

Sir,

Your obedient servant,

H. EARLE.

George-Street, May 8, 1830.

OBSERVATIONS ON THE ART OF MODELLING,

As connected with the Medical Profession; with Remarks illustrative of the general Utility to which its Cultivation may be rendered available.

By JOHN ELDERTON, SURGEON.

—

To the Editor of the London Medical Gazette.

SIR,

It was with pleasure I perused, in your interesting miscellany of last week, a communication by Mr. Alcock, relating to the topic of anatomical models; and happy I was to learn that encouragement was held out, to the junior members of the profession, for the cultiva-

tion of an art which merely demands unbiased reflection to convince the world of the advantage to which it may be rendered subservient. A residence for some years at the Northampton General Infirmary, afforded me both time and opportunity to cultivate a process which, having for its general scope the elucidation of the various parts of the body, either in health or disease, I have ever considered strictly professional; and when I inform my brethren that, at my removal to town in the year 1822, I paid Messrs. Pickford and Co. for the carriage of 3 tons 17 cwt. of coloured anatomical models, the profession will be perhaps disposed to allow that the construction of such a collection must have both familiarized me with the art of their preparation as well as furnished reflection collateral to the subject. I trust I may, however, be pardoned for remarking, before entering more fully on my paper, that having repeatedly suggested to individuals arguments demonstrative of the utility of the art, to learn that patronage now sanctions a measure which was viewed as hypothetical, accords with the too often experienced truth—namely, that the specific merits of any suggestion relating to a profession, should alone claim unbiased consideration from its members, in place of its successful issue depending on the vague decision of any popular individual, less scientific than perhaps remarkable for worldly success and a blind devoted deference from mankind.

In regard to the facility with which a knowledge of the process of casting may be acquired by a student (and of which I will first treat), I perfectly coincide with Mr. Aleock, that there are no obstacles to encounter but what common capacity may surmount; at the same time, circumstanced as the generality of medical students are in towns, unless numerous auxiliaries were prepared, the accomplishment of such an object would prove any thing but what I have in view. That my observations relate to the art of elucidating the various parts of the body, healthy and morbid, through the medium of coloured anatomical casts, the reader will by this time have understood; always having considered the artificial representations emanating from the mere modelist, howsoever ingenious and productive of effect they may prove,

much inferior to the characteristic fidelity of nature, which the science of casting may be brought to accomplish. That casts may be taken of the various tissues of the human body as faithfully correct as the impression of a seal is imparted to its wax, I shall be most happy to prove, by either transmitting for inspection any I have made, or by taking impressions, if required; but as there are countless examples connected with the method of illustrating the nerves, arteries, and bony processes, &c. that demand management totally distinct from common muscular casting, and which I only attained a knowledge of from time and various experiments, I shall not, perhaps, be expected to explain the same without some motive beyond the inducement incidental to a communication of the present character.

Affording, perhaps, a test of the fidelity with which casts may be constructed to imitate nature, I should imagine no process of modelling could preserve the hair in the eyelash with its characteristic regularity, as displayed in many casts; while the smallest demonstrable capillary nerves, and fibrous structure of the muscles, are as accurately represented as the outline of coarser parts.

Not to omit what I have ever estimated would prove a considerable advantage attendant on students preparing these representations of the anatomy of the body, is, that to complete the cast, and give the various colouring tints to its surface, the part, while under dissection, must be minutely and accurately impressed on the memory; otherwise the outline of the cast, when taken from the mould, will by no means in all cases bespeak its parts; and from this source, as a necessary consequence to represent the several parts in correct colours, the mind is usefully exercised in this second process, to a degree beyond, perhaps, what was the case when dissecting and preparing the part.

With respect to the advantage to be derived, both to the public and the profession, from a liberal cultivation of the subject of my paper, many examples may be adduced; but the witnessing the mode of taking a few representations in plaster, would impart more insight into the mechanical part of the art than any information to be imparted by word.

As a considerable portion of the time

of a medical student, upon entering on his professional career in our larger towns, is occupied in dissecting-rooms, on principles of instruction at first limited to the knowledge of familiarizing himself with the relative bearings, names, and connexions of the various parts composing the human body; I am prepared to prove, that such necessary fundamental acquisitions of the science may be obtained both with facility and accuracy as soon, or sooner, from access to such casts, than from the routine system of examination, casually, perhaps, presenting a view of any part a mere limited number of times to a student in a dissecting-room. That daily access to such exhibitions would familiarize the mind with the relative bearing of parts, and stamp the same on the memory to an advantage beyond the mere temporary inspection from manual dissection, can scarcely, it would be supposed, be questioned; and as such initiatory dissections are totally independent of any researches, either physiological or pathological, I conclude the suggestion can only meet with opposition from individuals whose unacquaintance with the merits of the subject renders them incompetent to judge with impartiality. That the arguments and opinions of professional writers from the earliest period, present sentiments in reference to the necessity of cultivating dissections, apparently opposed in part to what I have recommended above, I do not for a moment contend against; and were any of your readers to conclude for a moment that I was not fully impressed with the necessity of medical students cultivating the exercise of the hand by dissections, or that I did not consider personal examination of the body by students as a branch of professional education of incalculable benefit both to science and the community, I should be misinterpreted, merely having had in view the aim of shewing, that while artificial measures are found adequate to familiarize the student with the coarser structure of the animal organization, the mere plea of exercising the hand is but a chimera when we reflect on the limited sphere of operative surgery occurring to so few in after-life.

Having during my stay at the infirmary, as well as since my retirement, had the care of instructing several medical gentlemen, I hesitate not a mo-

ment to affirm, that the information to be derived from anatomical coloured casts is not solely limited to the means of imparting structural information, but that by the extensive scope of references such collections afford opportunities of adverting to, both physiological and pathological axioms may be elucidated to an advantage that few dissecting-rooms afford opportunities of equaling.

With professional gentlemen residing in the country the possession of such casts would be soon practically estimated, for I need not remind men of my own standing how treacherous is the memory in respect to points bearing on anatomical reference. Were students, therefore, to prepare these models, their attention would not only be necessarily ensured, as before explained, but useful illustrations of the more essential parts would be in their possession, ready to refer to under emergencies of future practice. The accuracy with which the anatomy of the parts connected with the several varieties of hernia and vascular structure may be shewn, is little perhaps imagined by those who have not witnessed the productions of the art.

As affects the interest of the community in promoting the cultivation of anatomy—a most essential branch of a valuable profession, a minute acquaintance with the intimate structure of the human body may be patronized among its members with a direct and immediate diminution in the demand for human bodies, the present system of supplying which is so often revolting to the feelings of human nature, than it would be absurd to suppose it could long continue on so precarious a basis as that at present existing.

To conclude, I cannot imagine a more useful or splendid exhibition than might be formed, were the nation disposed to patronize the art contemplated; and when we reflect on the numerous specimens of disease occurring at our metropolitan hospitals, opportunities would occur of perpetuating cases, the possession of which would not less tend to promote medical science, than their loss is now indirectly experienced by the public. But when it is considered that, contrary to many other pursuits, the various processes of such an art must, to obtain completion, pass entirely through

the hands of the same individual; and that extensive medical knowledge, as well as mechanical tact, are requisite accomplishments for a person to be able to avail himself physiologically of the several circumstances a part may be rendered capable of professionally elucidating, it cannot be supposed individuals would be found to enter upon the fatigue and confinement of such a pursuit to the necessary exclusion of other sources of practice, excepting under circumstances of a liberal remuneration.

I am, Sir,

Your obedient servant,

JOHN ELDERTON.

Northampton, May 4, 1830.

CASE OF UMBILICAL HERNIA TREATED BY LIGATURE.

By ROBERT COWAN, Surgeon.

IN 1827 I was called to visit a child about three months old, which, on examination, was found to have an umbilical hernia, as large as an hen's egg. No herniary tumor existed at birth, nor for at least ten days afterwards; and the tumor had been noticed only the day before I saw it, by the child's mother, after the nurse (who in all probability conceived it to be owing to her carelessness) had left the house. The child had experienced repeated attacks of colic, attended with such an irritable state of the bowels, as to require opiate clysters and opiates to be frequently administered.

Attempts were made, by means of a compress and bandage, to keep the hernia reduced, and allow the aperture through which it had passed to become obliterated; but these proving ineffectual, the plan of applying half of a ball sufficient to cover the opening, and securing it by means of adhesive plaster, as recommended by Sir Astley Cooper, was tried, and with equal want of success. These attempts proving abortive, and the frequent renewal of the bandages being a great source of annoyance to the infant, it was resolved, notwithstanding the arguments advanced by Scarpa and others against the employment of the ligature, to attempt a cure by its means, in the mode adopted by Desault.

Accordingly, the child having had the previous day a dose of castor oil, with the assistance of my friend Dr. John Couper, the hernia, which was entirely intestinal, was reduced, and a small round ligature firmly applied around the neck of the sac, as close to the abdomen as possible. This gave little uneasiness; and a warm bath, prescribed in the evening, procured a comfortable night. On the third day a fresh ligature was applied, which produced sloughing of the part: on the fifth a third ligature was applied; and on the seventh day from the operation the included portion dropped off, leaving a small sore, which was dressed with dry caddice, a small compress, and a strip of adhesive plaster.

In another week the sore was entirely healed, but the compress and strap were continued for three weeks longer, at which time the aperture in the umbilicus was as completely and as firmly closed as in children of the same age.

I have since occasionally examined the part, and the cure is complete.

In the umbilical hernia of children, the protruded parts escape directly through the umbilical ring; in that of adults, unless the hernia has existed from infancy, the aperture is in the abdominal parietes near the umbilicus, never in the umbilical ring itself.

What distinguishes the umbilical hernia of childhood from every other species of hernia, is the strong natural tendency to contract, which exists till about the age of nine years, in the aperture through which the viscera protrude; and which contractile tendency, greatest immediately after birth, gradually decreases till about the period mentioned, when it ceases altogether.

In some instances umbilical hernia is congenital, and when so, is not unusually accompanied with malformation of the abdominal muscles. Most frequently, however, it first commences about the age of two or three months*, and unless attended to is apt to increase in size, and prove a continual source of irritation and annoyance. The inherent tendency in the aperture through which the viscera pass to contract, is in many cases strong enough to produce a natural cure, but more generally the aid of art is requisite.

Two plans of cure have been pro-

* Desault.

posed, viz. compression and the ligature. By means of the former, the protruded viscera are reduced and the aperture kept closed, either by bandage and compress, or by introducing a segment of a small ball into the opening. It is quite obvious that this latter mode is objectionable, from the ball producing precisely the same kind of resistance to the closure of the aperture as the viscera did. The plan of cure by compression is most generally adopted.

The other method of cure is by the ligature, as in the preceding case; and this may either be employed when compression has failed, or, as was the practice of Desault, in preference to it.

Celsus, in his Chapter de Umbilici Vitiis, describes the mode of curing umbilical hernia by the ligature. He, however, makes no distinction between umbilical and ventral herniæ; and so far from being aware that this operation was likely to be most successful with infants, he expressly forbids its performance on any below the age of seven, or above that of fourteen years*. The operation by the ligature seems not to have been practised in modern times till Saviard operated, and that successfully, on two children under fourteen months old. His example was not followed, and till the time of Desault was entirely neglected.

Desault revived the use of the ligature in the umbilical hernia of children, an operation founded on a correct idea of the anatomical structure of the part; and especially on the fact that the opening through which the viscera pass has the strong natural contractile tendency already alluded to. It has been alledged that Desault revived the operation described by Celsus; but the absurdity of this idea is rendered apparent by the quotation already made from that author's works. Desault operated on at least fifty patients, none of whom he lost; and from the result of these he has drawn the following conclusions: 1st, That the sooner after birth the operation is performed, the more certainly will a cure be effected; 2dly, That at the age of four years a cure is effected with some degree of difficulty; and, 3dly, That, at nine, the contractile tendency in the

aperture being almost entirely lost, the cure is nearly impossible.

The operation for the cure of umbilical hernia by the ligature has, since the death of Desault, fallen into disuse; and to this the opinion of Scarpa has, in no small degree, contributed.

It has been objected to this operation, that it is sometimes ineffectual. This is certainly the case if performed when the contractile disposition in the ring has ceased; and the same objection may with equal propriety be asserted of the mode by compression.

Others alledge it to be dangerous, especially if a portion of intestine is included in the ligature. When properly and carefully performed, this objection can never occur. Inflammation, irritation, and even death, it is said, have followed the operation, even when every thing has been well done. This is very possible, and yet in Desault's fifty cases no death took place.

When the ligature has succeeded at first, it is alledged the cicatrix has afterwards given way, and a hernia formed a second time.

I confess it was with surprise I found, in the work of Scarpa, this opinion attempted to be supported by a supposed analogy between the operation of the ligature in the umbilical hernia of children, and the barbarous treatment of inguinal hernia by the ligature of the hernial sac and spermatic cord in the adult. It is stated that, in this latter case, the cicatrix is apt to give way, unless a truss is continually worn.

The two cases bear no analogy to each other: in the inguinal hernia the opening possesses no disposition to contract, while that in the umbilical hernia of children does so: and, besides, when a cure has followed the use of the ligature in umbilical hernia, the navel is at least as firm as in those children who never have had this disease.

M. Cartier also, overlooking the anatomical structure of the navel, declares, that since "la cicatrice n'empêche pas toujours la recidive de la hernie inguinale ou crurale chez les sujets qui en ont été opérés, on ne doit pas, à plus forte raison, compter sur une guérison radicale après l'opération de la hernie de l'ombilic chez les enfans."

This opinion is not corroborated by experience; for, as stated above, the navel is as strong after the termination

* Nam curationi neque infans, neque aut robustus annis aut senex aptus est sed a septimo fere anno ad quantum decimum.—*Celsus de Medicina*, vol. ii. p. 327.

of the cure of the umbilical hernia by the ligature, as it is in those infants who have never had hernia.

Dupuytren has operated on umbilical hernia in children by the ligature many times, and always with the happiest effects; and many cases are scattered over the pages of our numerous periodicals in which the operation met with equal success.

In the umbilical hernia of children, I would, in deference to the expressed opinion of the profession, first attempt the cure by compression merely; if this failed, or was very annoying to the child, from the difficulty of retaining the necessary bandages *in situ*, recourse would be had to the ligature, as in the preceding case. From the experience of Desault, as recorded by Bichat, it is fair to infer that, under proper limitations, this operation is both safe and efficacious; and though, in the greater number of instances, a cure is possible by compression alone, still there are others where this fails, and in which the ligature will succeed*.

MEDICAL GAZETTE.

Saturday, May 15, 1830.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."—CICERO.

THE KING'S HEALTH.

WE regret to say that his Majesty's health has not improved: the continued disturbance of the circulating and respiratory systems has now been for some time associated with dropsical effusion, and the hope held out at an earlier period that the attack might prove transient, is thus removed.—About ten days ago the operation of puncturing the legs was performed by Mr. Brodie, who has since frequently visited his Majesty. Scarification had previously been practised by Mr. O'Reilly.

As other reports have been industri-

ously circulated, we may take the opportunity of stating, that Mr. Brodie is the only one whose assistance it has been deemed expedient to have recourse to in addition to that of his Majesty's ordinary attendants. The circumstance which gave rise to the report that Mr. Wardrop had been sent for, consisted in his having seen his Majesty on one occasion when on a professional visit to one of the household. The *on dit*, though we can scarcely credit it, is, that Mr. Wardrop subsequently offered to the medical attendants the benefit of his opinion.

ANATOMY.

ON Monday last Lord Calthorpe presented a petition from the members of the Westminster Medical Society, praying for some measure in protection of the study of anatomy. His Lordship gave notice that it was his intention, on an early day, to bring forward a bill having for its object to grant the relief sought for by the petitioners.

Already has the note of alarm been sounded, and we shall doubtless have a repetition of the same trash with which the newspapers, with one or two honourable exceptions, teemed last season. An evening paper makes the mere notice the text for a homily, in which the writer wisely remarks that the French are supposed to know their profession tolerably well, and asks why forsooth, should English surgeons be better off than they? Blockhead! had they enjoyed one half the advantages possessed by the French, the event which gave rise to his stupid article would never have occurred.

ROYAL WESTERN HOSPITAL.

A MEETING of rather a novel description took place a few days ago, at the Yorkshire Stingo, in reference to the institution having the above imposing designation. We are informed by a gentleman who was present, that the scene of confusion beggars all description. Sir Charles Scudamore attributed the bankrupt state of the funds to the mismanagement of Mr. Sleight. This,

* From the Glasgow Medical Journal.

of course, led to recrimination, when Mr. Sleigh observed, with some *naïveté*, that the *success* which the Hospital had met with was entirely owing to his influence and exertions. The extent and nature of the success will be best understood when we mention that there is an immense outstanding debt, with no adequate funds to meet it. To this we may add, for the satisfaction of those connected with the Institution, that a few days ago a gentleman, who had become a governor on the same footing as he might have done to any other charity, but without taking any part in its management, received a letter informing him that as the committee had refused to pay the apothecary's salary, he (the governor) would please to do so, or favour the applicant with the name of his solicitor.

Mr. Sleigh is the gentleman who, backed by the *Lancet* (which, by the way, has since deserted him), a few years ago undertook to reform St. George's Hospital, and save—we really have forgotten how many thousands per annum.

SINGULAR EFFECT OF HEAT.

MR. WAKLEY'S dinner party at the Freemason's is postponed on account of the heat of the weather—"a public dinner in the summer is an intolerable nuisance" (*Lancet*, May 8th). It is impossible to imagine a more complete exposure of the estimation in which our opponent is held than this abortive measure has proved: we had but to state with whom it originated, and all by general consent declined to lend it their countenance. To use the words of our contemporary himself, "this, we hope, will prove a salutary lesson to those very silly persons who deny the influence of the independent part of the medical press."

By the way, it is lucky this excuse was made before the weather became so intolerably cold again.

NEW ST. GEORGE'S HOSPITAL.

THIS magnificent building advances rapidly, and the front towards Grosvenor-Place, constituting, with what is already finished, two-thirds of the entire pile, will be completed in a few months. A public meeting was held last week in aid of the building fund—his Grace the Archbishop of Canterbury in the chair, supported by numerous noblemen and

gentlemen—on which occasion nearly 2000*l.* were subscribed in the room.

Among the improvements of the new hospital, the arrangements for the convenience and advantage of the pupils are not the least considerable: there is a dead house fitted up as a theatre, where post mortem examinations are regularly carried on; while a museum and library, as well as a lecture-room, are in preparation, and will be completed before October, for the purpose of forming an efficient medical school.

PROPOSED TAX ON SURGICAL DIPLOMAS.

Unto the Honourable the Commons of the United Kingdom of Great Britain and Ireland in Parliament assembled, the humble Petition of the Royal College of Surgeons of Edinburgh;

SHEWETH,

THAT your petitioners have observed, with the greatest regret and alarm, that it is proposed to Parliament to exact, by a stamp-duty, a tax of 10*l.* upon the "admission or license of any person to be a member or licentiate of any College of Surgeons."

Your petitioners beg leave respectfully, but most earnestly, to represent, that the acquisition of a proper medical and surgical education necessary for all those who undertake the duties of general practice, requires a long period of time, and is attended with a very heavy expense, for which it is long before any adequate return can be obtained, and that the class of young men educated for surgery possess very limited means.

It has long been well known, that the education of those who apply for licenses and diplomas has been in many respects defective; and the different colleges and public bodies who have the power of granting these testimonials, have for some time past, and particularly of late, endeavoured to remedy this defect, by extending the course of study required from those to whom diplomas or licenses are given. The greatest obstacle which your petitioners, and it is believed the other public bodies, have encountered, in effecting this desirable object, has arisen from their knowledge of the difficulties imposed upon young men, by the increase of expense necessarily at-

tending it; and they have carefully avoided adding any thing to this expense, except what may be absolutely required to obtain the improved education. In proof of this they may mention, that no addition has been made for nearly a century to the fee required in obtaining a diploma (which amounts to 6l. 5s.); so that were the proposed stamp-duty imposed, the expense of obtaining this certificate, already it is believed as large as those applying for it can afford, would be nearly trebled.

In these circumstances, this tax could not fail to be most oppressive to those applying for surgical diplomas.

Your petitioners have also to represent, that a diploma in surgery, although at present generally taken by those educated at the different medical and surgical schools, is a mere certificate of qualification, not conferring any privilege, and is not required by law to be possessed by those who practise surgery or medicine in the greater part of the United Kingdom. In these circumstances, there seems great reason to fear, that the increased expense will absolutely prevent a large portion of medical and surgical students from taking a diploma; and they will thus be deprived of the motive to go through the full course of education which they at present follow. In this way, the interests of the community will be materially injured by the diminution of the number of properly qualified practitioners, and by the increase of the already too great number of the ill-educated and irregular; and the efforts which have been made, and are now making, to improve the education of surgeons, will be materially counteracted and impeded.

In the opinion of your petitioners, the proposed duty will operate as a tax for the prevention of the improvement and proper qualification of practitioners.

Your petitioners conceive, that even were the number of diplomas annually granted maintained at its present rate, the amount of the tax would be of little importance to the revenue; and they are satisfied that the diminution which it is likely to occasion, would render it even less productive than is anticipated.

Your petitioners also strongly feel, that the proposed tax, by lessening the number of diplomas, would materially diminish their funds, which they have hitherto applied in promoting medical

and surgical science, by the purchase and formation of extensive and valuable collections of anatomical and pathological preparations, and would involve them in great difficulties in the completion of the undertaking they have entered upon, of building suitable accommodation for rendering these preparations useful to the Medical and Surgical School of Edinburgh—a work which they will not be able to complete, even by the expenditure of their whole present funds, and which they commenced in the belief of the continuance of their present annual income:

Your petitioners therefore earnestly hope, that your Honourable House will take the above statement into your serious consideration, and that you may be induced to abstain from sanctioning a measure which will not, in their opinion, produce any good effect, and which they cannot but regard, for the reasons they have stated, as very oppressive to those engaged in the study of medicine and surgery,—as detrimental to the improvement of medical and surgical education, and therefore injurious to the community,—and as prejudicial to the interests of your petitioners.

May it therefore please your Honourable House to take the above statement into consideration; and to grant your petitioners such relief in the premises as to your Honourable House shall seem meet.

[The Town Council of Edinburgh have also petitioned against the imposition of this tax, and a deputation from the London College of Surgeons have had an interview with the Chancellor of the Exchequer on the subject. There is reason to believe that the measure will be abandoned.—*Ed. Gaz.*]

ROYAL INSTITUTION,

Friday, May 7, 1830.

BENJAMIN BOND CABBELL, Esq. F.S.A.
VICE-PRESIDENT, IN THE CHAIR.

Geodesical Survey.

MR. FARADAY “on the measurement of a base in Ireland for the geodesical survey now in progress under the direction of Lieut.-Col. Colby.” Most persons are aware that, for many years, tri-

gonometrical surveys have been carrying on by government, both in this country and in Ireland, to a very considerable extent; but few are conscious of the difficulties which occurred in rendering the measures absolutely accurate, or of the very masterly manner in which these have been overcome, by the construction of a compensation rod; in which the different expansive properties of different metals have been taken advantage of, to correct those variations which changes of temperature will cause under all ordinary circumstances. One of these compensation rods, which has been made for the East India Company, and which we think it was stated would cost 1000*l.*, was exhibited; it consists of a case, about sixteen feet or upwards in length, containing brass and iron rods, supported on rollers, with microscopes, telescopes, &c. attached, so that compensation to the 10,000th of an inch is easily effected; and although mere verbal description can give but a faint outline of it, some idea of its importance may be gained from the observation of M. Arago, the celebrated philosopher, who, when the plan was mentioned to him, retorted, "*Why the principle is perfect, but who can make it?*" Messrs. Sims and Co., the very philosophic mechanicians, have, however, succeeded in constructing the instrument, and with it a new base has been measured in Ireland, by which the accuracy of the previous triangulations has been proved, and a fresh point gained, from which other surveys are carrying on. The plans are drawn on the magnificent scale of a mile to six inches, and 600 persons are employed in the work. It may, perhaps, be thought that, in the measurement of land, and especially of an entire country, a less degree of precision would have sufficed; but when it is stated that, from those surveys carried on in England, Ireland, India, and elsewhere, the correct figure of the earth is to be deduced, and that an error in the first base, though very small, would, when multiplied into all the future calculations, involve an enormous fallacy, the necessity thereof becomes immediately apparent. Among the difficulties occurring, we may mention, that as a river, 460 wide, was included in the first base, the persons employed in the admeasurement were two days breast-high in the water. It is in these geodesical sur-

veys that the brilliant lime light, mentioned as exhibited here a few weeks since, has been employed; and as the sides of the triangles are 60, 85, 93, 98, 101, and that now measuring 107 miles in length, haziness of weather interrupts continually the process, so that those on watch have been anxiously engaged, not only days, but weeks, and even months together, looking through the telescopes, before the heliostadt burst into view.

In the library were the metallic bases of alumina and silica, which, although they have so long eluded the grasp of the chemist, can now be easily obtained from their chlorides. We also noticed some of the ashes brought from a druggist's shop at Pompeii, mentioned in Brande's New Manual of Chemistry; and examined, with much satisfaction, Chancellor's very ingenious new clock escapement.

On Friday next, the subject of Lithotrity, illustrated by experiments with the apparatuses of Civiale and Heurteloup, will be introduced by Mr. Gilbert Burnett.

HOSPITAL REPORTS.

EDINBURGH ROYAL INFIRMARY.

Singular Malformation of the Penis—Remedied by Operation.

F. H. æt. 26, admitted under the care of Mr. Liston, February 9th. The whole extent of the urethra anterior to the pubes is exposed superiorly, there being a wide fissure through the corpora cavernosa and glans. The penis is retracted considerably, so that the posterior part of the fissure lies beneath the symphysis pubis; the integuments over the pubes are of a dusky red colour, and are extended laterally into two loose folds attached to the margins of the posterior extremity of the fissure. The numerous lacunæ of the urethra are beautifully distinct, and the mucous surface is seen covered by their secretion. When the patient makes water, the urine, after emerging from beneath the symphysis pubis, divides into numerous small streams, some of which spread over the sides of the penis, whilst others pass along the exposed urethra. No opportunity has been afforded of observing the appearance of the parts during erection.

The patient cannot be prevailed on to give any satisfactory account of the malformation,

and persists in attributing it to an injury of the back, followed by suppuration in the cellular tissue along the dorsum penis.

11th.—The callous margins of the fissure were carefully pared, and, a catheter having been introduced, the raw surfaces were retained in accurate apposition by several points of interrupted and twisted sutures. The catheter was allowed to remain, and, being fitted with a stop-cock, the urine was thereby evacuated at certain intervals.

On the second day after the operation, there were appearances of slight inflammation around the wound, but union had nevertheless occurred at several points. Urine passed through the catheter.

17th.—The sutures have been removed, and the wound is almost entirely united. The catheter has been withdrawn, but is always replaced when the patient desires to void his urine.

On the 8th of March the union was almost complete, but two minute apertures remained at the posterior part, through which several drops of urine escaped when the patient made water. There had been no constitutional disturbance during the treatment.

In a few days he was dismissed, complete cicatrization having occurred, and the appearance of the penis differing but slightly from that which the organ generally possesses.

He confessed that the malformation was congenital, and that the organ had been incapable of performing its proper functions. He also stated, in further explanation, that his mother, when pregnant, had gone to "draw water," and had been much alarmed by a hare suddenly starting up and placing its paw upon her thigh. This circumstance, he conceived, had caused a deformity of his penis, similar to that of hare lip; and, in confirmation, he stated that a mark of the hare's paw was visible on the inner side of his thigh. Certainly there was, in that situation, a *nævus* intimately resembling the print of a hare's foot.

Dislocation of Femur on Pubes.—Reduction on the Eightieth Day.

William McKenzie, *æt.* 24, admitted under the care of Mr. Liston, March 5th.

The right lower extremity is considerably shortened, and the toes are much everted. The motions of the thigh are confined, the head of the femur projects in the groin, and, on the thigh being moved, can be distinctly felt rotating on the os pubis towards the outer side of the femoral vessels. The trochanter is depressed, the muscles are somewhat wasted, and the whole limb is much more feeble than the other.

States that, eleven weeks ago, he fell from the rigging of a vessel, a height of nearly fifty feet, and lighted on the right trochanter; immediately afterwards the limb was ob-

served to be shortened and the toes everted, and these appearances have ever since continued. The case had been treated as fracture of the os innominatum without dislocation.

March 8th.—Yesterday the patient was brought into the operating theatre, and Mr. Liston stated that the symptoms of dislocation, upwards and forwards, were so distinctly marked, that there could be no doubt as to its existence; and that, notwithstanding the long period since it had occurred, he considered it his duty to attempt reduction. Powerful extension was accordingly made by pulleys, along with rotation inwards; and after much exertion, reduction was accomplished. A tobacco enema had been previously administered. The knees and ankles were bound together by means of a broad roller, and the patient carried cautiously to bed.

Next day there was considerable swelling of the upper part of the thigh, but it soon disappeared. The bandages were continued for some days; he regained in a great measure the natural motion of his limb, can now support on it a considerable part of his weight, and walks in the ward by the aid of a crutch.

GUY'S HOSPITAL.

Lumbar Abscess.

THE three following cases of lumbar abscess were lately treated in this hospital by Mr. Key, and shew the result of a practice which has been strongly advocated of late years by M. Lisfranc, and other continental surgeons, in all chronic abscesses, viz. the application of a large number of leeches at first, which are to be repeated, if necessary, more than once. It is stated, that under this plan of treatment, the matter of these abscesses very frequently becomes absorbed, and that even if this should not take place, still the matter may be safely evacuated by a free opening, and without the risk of that dangerous inflammation of the cyst, and hectic, which too commonly supervene and terminate fatally when this is done without the previous depletion.

CASE I.—Elizabeth Brider, *æt.* 20, unmarried, admitted 9th Dec. 1829.

There is a swelling by the side of the spine in the left loin, which fluctuates, and is very tender. It was first observed only a fortnight ago, though the patient has had pains there for the last three years, more or less. Her health, she says, has been good; she looks well. Pulse 80. She has never yet menstruated, but is subject to periodical headaches.

12th.—Thirty leeches were applied yesterday to the swelling; they bled freely,

and have much relieved the pain; however, the tumor remains as large as before. Pulse 116, soft. Tongue moist.

14th.—Less pain; tumor softer, and a little smaller. Pulse 103; tongue clean; health good.

Rep. Hirudines, xxx. lumbo.

17th.—The swelling is larger, but not nearly so painful; her pulse is very weak, and face pallid from loss of blood. An opening by the lancet was made; about 5jss. of thin pus, mixed with curdy flakes, were evacuated.

22d.—For the last day or two she has had severe headache, with sickness and loss of appetite; a quick, frequent pulse; hot skin; white tongue; bowels confined, and general languor and debility. There is a little discharge from the abscess; not much local pain. For this she took the saline mixture, with hyoseyamus, and a dose of castor oil. This morning there is, besides the above, great sickness. Pain in right side of chest and scrobiculus cordis, aggravated on inspiration, and a dry cough.

Cucurbit. cruentæ lateri dextro, ad 3ʒj.
E. Lyttæ postea. Opii. et Calomel, aa.
gr. j. h. somni et mane. Rep. Mist.
Salin.

23d.—Has passed a restless night; her face is flushed; tongue dry and brown; pulse 132, quick and sharp. The pain in chest, difficult and quick breathing, the sickness, and cough, remain as before. Bowels not open. Auscultation shewed crepitation in the middle and lower part of right lung behind, and the mucous rattle above.

Pulv. Rhei. c. Calomel, gr. xv. stat.
Hydr. Submuriatis, gr. j. n. m. que.
Julep. Ammon. Acet. c. Liq. Antim.
tart. ʒxxv. 6tis horis. Omitantur
alia.

24th.—Had a very bad night; bowels were once open; a fluid stool, nearly black; pulse 130, with some sharpness; tongue dry and coated, less brown, the edges red; the thoracic symptoms seem quite subsided, at least they are not at all complained of. There is now pain and tenderness below the epigastrium, rather indicative of peritonitis. There is severe headache, and great restlessness, amounting at times to slight delirium. The discharge from the abscess is so copious that it was this morning found pouring over the side of the bed. It is very fetid.

Hirudines xx. abdomini st. Cataplasma.
postea.

Calomel, gr. ij. Extr. Hyoseyami, gr. iij.
4tis horis.

Vespere.—Abdomen still tender, and there is some tension; bowels not open since last reported; tongue as before; pulse very

small and weak, 123; face bloodless; she is not quite sensible.

25th.—Tenderness less; two scanty stools since last night; otherwise as before.

26th.—Remains nearly the same; bowels not properly open; only a small quantity of brownish fluid in the stools. She rambles a great deal.

Calomel et Opii. aa. gr. j. 6tis horis.

27th.—She is quite insensible, and cannot be made to take any thing, either food or medicine. Bowels not open; tongue not dry, but coated with dirty white, and with red tip and edges. Pulse very small, 150; slight jactitation of the fingers.

28th.—She lies in the same low rambling state; pulse 160; abundant discharge from the abscess. She shrinks from pressure in its neighbourhood. Bowels open yesterday after a dose of castor oil. It was to-day ascertained that she has had a scalding in making water, which now dribbles freely from her; there has, moreover, been on the external genitals a sort of erysipelato-phlegmonoid inflammation, upon which are a few portions of superficial slough. Nothing satisfactory can be learnt about this, except that it began a week ago, the nurse supposes from the heat and moisture of the poultice which has been on the abdomen. She had no discharge or disease in the genitals previously.

Julep. Ammon. subinde. Continr. pilulæ.

Poultice to the abdomen and abscess, and a soft bread poultice to the pudenda.

29th.—This morning she lay quite insensible and pallid; there was subsultus tendinum, and no pulse in the wrists. In the afternoon she died.

Post-mortem Examination 25 hours after Death.

Chest.—Both lungs red with blood, and both firmly adherent to the parietes by tough old adhesions, especially the left lung. The right was less so, and about the lower half of this lung, on the pleura and reflected pleura, was seen a layer of recent lymph: here, also, there were a few old adhesions. The lung itself, at this part, was somewhat like a spleen, easily lacerable. There were no tubercles; the heart was sound, and firmly contracted. In the pericardium 3j. of serum.

Abdomen.—Singularly tough old adhesions between the liver and diaphragm, chiefly on the left lobe of the liver, which was torn in attempting the separation. The liver itself was sound; spleen healthy; the intestines distended with flatus, and the small ones contained here and there streaks of nearly black viscid mucus. There was bright redness, in considerable patches, on the mucous

membrane of those small intestines which were in the hypogastric and left iliac regions. There was no trace of recent peritoneal inflammation.

The abscess was now looked for carefully, and found situated behind the quadratus lumborum muscle, between it and the integument behind. The muscle was unaffected; it was lined by a thick, red, granular membrane, and did not appear to be capable of containing more than 3ss. of fluid. No bone was found denuded; but a very accurate examination of this part could not be made as the body was inspected at home, in the presence of the friends of the deceased.

Uterus and its Appendages.—The vagina was pervious; there was no hymen. The peritoneal covering of the uterus was red; its substance was very red and inflamed, and its cavity contained 3ss. of pus, like thick cream. The fallopian tubes were knotted, like strings of beads, which were found to be softened tubercles. There was a corpus luteum in the left ovary, and a small hydatid in the broad ligament of the same side.

CASE II.—Robert Cheese, æt. 26, admitted 18th Nov. 1829.

This is a case of lumbar abscess, of common history and characters. The first symptoms of pain and heaviness in the back commenced three months ago, and now there is distinct fluctuation in the right lumbar region. He has the usual scrofulous and hectic aspect; tongue whitish and moist; pulse quick and frequent. It appears that this abscess was called into action three months ago by a fall down a flight of stairs, in which he struck his loins several times against the edge of some of the steps.

Nov. 19th.—To be confined to bed; to take Julep Ammon. Acet.

Hirudines, xxx. lumbo.

22d.—Felt great relief from the leeches: before their application he was in considerable pain, and could not move the hip-joint without increasing it, nor could he bear pressure. A diarrhœa has come on since yesterday, attended with griping and tenesmus.

Ordered, Pulv. Doveri. gr. v. post sing. sedes liquidas.

23d.—Diarrhœa ceased; abscess smaller, and less painful; cheeks flushed; pulse less irritable and strong than when he was admitted; tongue moist, and a little white.

Rep. Hirudines xxx. tumori.

25th.—Easier since the leeches; can now move the hip-joint without so great pain; pulse 92, weak and small; tongue pale and moist; bowels disposed to be relaxed but for the Dover's powder, which he continues to take when necessary.

30th.—Rep. Hirudines xxx lumbo.

Dec. 7th.—He is free from pain, except a little on pressure; no fluctuation can be felt, but the venter ilii is much thickened; pulse 88, quick and compressible; tongue pale, but clean; sleeps well, has no cough, but perspires a good deal towards morning.

Ordered—Sulph. Quinina gr. j. ex Infus. Rosæ co. ter die.

14th.—Over the back of the ileum a little matter is felt; the ala of the bone is nearly two inches thick, and tender; he is stronger than he was a few days ago.

Hirudines xx supra cristam ilii.

17th.—The last leeches have again relieved him, and a very little matter now remains; the bone is still thickened.

Empl. Lyttæ minimum loco affecto.

21st.—There is matter behind, which appears increasing towards the edge of the longissimus dorsi. His health is improving.

Hirud. xx. parti affectæ.

24th.—Improved by the leeches; there is less matter, and the bone is less thick; pulse frequent, but soft; tongue moist; appetite better.

30th.—No fluctuation can be felt; he continues the quinine.

Feb. 16th.—During the last month he has moxas and a seton over the dorsum ilii, which have almost restored the bone to its natural thickness: he has been up the last few days.

March 18th.—Dismissed, very little thickness of the bone remaining.

He came to the hospital a month afterwards to shew himself: he had had no return of the disease; had gained strength; and had even been able to ride on horseback in his employment of groom.

CASE III.—W. H. Graftey, æt. 18, Nov. 18, 1829; presents the usual characters of a scrofulous habit; there is a distinct fluctuation in the right lumbar region; the abscess is very painful, and his attention was first directed to the part a month or three weeks ago; previous to this, however, he had some enlarged glands in the neck, which have suppurated, and are now open.

19th.—Hirudines xxx tumori.

24th.—Has derived no relief from the leeches.

Rep. Hirudines xxx.

Dec. 5th.—Is not at all benefitted by the leeches; the pain of the abscess is very severe; it appears too enlarging, and is of considerable size.

An opening of nearly an inch long was made, and let out about 3vj. of pus, not the

whole; the pain immediately ceased; the wound was closed, and bandage applied round the body.

Ordered—Julep. Ammon. Acetatis 6tis horis.

7th.—The rest of the matter (about 3vj.) was evacuated, and the wound closed as before.

9th.—He is free from pain, and sleeps well; pulse 120; tongue clean; bowels regular.

Pergat.

15th.—Last night the abscess burst, and a good deal of matter escaped; the first opening had closed.

17th.—Is very weak; there has been but little hectic since the discharge of the matter, which now issues freely into a poultice.

To have nourishment, beef-tea, meat, &c.

21st.—He is improving in health and in strength; there has been little, if any irritation from the opening of so large an abscess.

To continue; and to have porter, a pint daily.

23d.—To-day he complains of pain on pressure on the site of the abscess, and forwards towards the diaphragm. He does not feel so well; bowels not open.

Ordered—Magnesia and Salts in the morning if necessary; large poultice to the abscess; and Træ. Hyoscyami, 3ss. Magnes Sulph. 3ss. Mist. Salina, 3j. 4tis. horis.

24th.—Severe pain in left hypochondrium, aggravated by a full inspiration; quick pulse; white tongue; hectic flush on the cheek; bowels open.

Hydr. Submur. gr. j. Opii. gr. ss. Antim. tart. gr. ½. 4ta vel. 6ta qq. hora.

28th.—He has been very low and depressed since last report, coughing a good deal, with mucous expectoration, and having pain about the margin of the ribs on left side, increased in inspiration; and also pain in the neighbourhood of the abscess behind, which discharges copiously. Has had hectic flushes, but this morning he is pallid as death; pulse scarcely perceptible; tongue moist, gets no sleep, and is often insensible. He was ordered a little Ammonia, with Træ. Opii. m̄x. every two hours, or oftener, and some wine; however, he did not rally, but died on the afternoon of the same day.

The friends would not allow the body to be inspected. T.

DECLINED ARTICLE.

To the Editor of the London Medical Gazette.

SIR,

THE following I addressed to the Editor of the Lancet about a fortnight ago; and, as I

anticipated, he has neither inserted nor alluded to it in his veracious journal. If you have a spare corner in the Gazette, pray let this fill it.

I am your obedient servant,

SCOTUS.

"To the Editor of the Lancet.

"Sir,—Richly as the quackery of Mr. Long deserves to be stigmatized and held up to public ridicule, and much as the exercise of that relic of papal usurpation, the power of conferring degrees of all kinds claimed by the Archbishop of Canterbury, is to be deprecated, they cannot justify the wantonly libelling an ancient and respectable University, which in former days, Clarendon says, 'flourished under many excellent scholars and very learned men;' which, in more modern times, can boast of numerous distinguished individuals in every branch of science, who have either filled professors' chairs or received their education within its walls; and which, blameable as it may at one time have been, has long ago adopted and rigidly adhered to regulations, respecting medical degrees, which afford no reasonable ground of complaint.

"The assertion contained in a paragraph of your last number (April 17th), that 'the ancient University of Aberdeen had proffered a degree to Mr.,' or, as you style him, 'Doctor Long,' is without the slightest foundation in truth; and it is much to be regretted that a medical journal should be the medium of conveying to the public such a gratuitous falsehood.

"I am, sir,

"Your obedient servant,

"SCOTUS.

"May 4th, 1830."

Mr. Liston's Operations for the Restoration of the Columna Nasi.

A wrong date was appended to these cases as given in a former number. The first operation was performed in July 1828.

ERRATA.

In our report of Dr. Stevens's paper, page 218, col. 1, for "the blood losing its saline taste—of which circumstance the black colour is found to be a certain proof," read "the blood losing its saline impregnation," &c.

For "the various properties of the blood depend on its saline impregnation," read "various properties," &c.

And after "even when proper means are used," insert "to reduce the excitement," same page, bottom of col. 2.

LECTURES ON SURGERY,

Delivered at St. Bartholomew's Hospital,

By WILLIAM LAWRENCE, F.R.S.

— from 1832.

LECTURE XLI.

VASCULAR SYSTEM.

Wounds of Arteries, and various methods of arresting Hæmorrhage.

Loss of blood, or, as it is technically called, *hæmorrhage*, is one of the circumstances attendant on wounds which is sometimes dangerous, and even fatal; while it is always alarming to patients and to those around them, especially if they do not understand what ought to be done. The danger of bleeding is not confined to the very time at which the injury is received, or immediately after it; for the bleeding that immediately follows a wound may stop, but the hæmorrhage may be renewed at some distance of time, and the patient may die from its recurrence. Hence it is of great importance to adopt immediately such effective means in the wounds of blood vessels as shall prevent these dangerous consequences. Ancient surgery was very defective in this respect; for although we find in Galen and in other writers mention made incidentally of tying arteries, it does not appear that the practice was adopted generally; it seems, indeed, to have been rarely employed, and not to have passed into general use, which we should expect that it would have done, if the nature of so simple and effective a mode of proceeding had been well understood. Thus we find that the older surgeons, for the purpose of arresting hæmorrhage, employed *compression*, the application of substances possessing or supposed to possess *styptic* properties, and even the *actual cautery*. Now we cannot wonder that they were afraid of performing any of

the great operations, when their means of remedying bleeding were so very imperfect—when the only way in which they could prevent a person from bleeding to death, after amputation for example, consisted in burning the surface of the stump, in order to sear and close up the divided vessels.

The celebrated French surgeon, Ambrose Paré, has the honour, if not of inventing, at all events of re-introducing into practice, and bringing into general use, the plan of tying wounded blood-vessels;—and when we consider how important this is—how much better many operations must have been performed with the advantages derived from this mode of arresting the hæmorrhage, and how much simpler the treatment of wounds must have been under this mode of proceeding, we cannot be surprised that this surgeon should have considered that the thought of employing ligatures came to him by a kind of inspiration.

The process adopted by nature for arresting hæmorrhage, and the mode in which ligatures act in accomplishing the same purpose—in fact all the circumstances connected with bleeding, and the mode of arresting it, have been very carefully investigated in modern times, so that we may consider this part of surgery as brought nearly to a state of perfection.

Arterial Hæmorrhage.

Arterial hæmorrhage is distinguished from venous by two circumstances—*first*, by the colour of the blood, which is a bright scarlet; *secondly*, by the circumstance of it being thrown out in jets. A wounded artery is said, technically, to bleed *per saltum*, which means by leaps or jumps. Now we cannot understand this phrase quite in a literal sense, for the blood is not thrown out exactly in a series of single projections: the stream of blood from a wounded artery, like that from a wounded vein, is uninterrupted; but the stream rises higher, or is projected farther from the body at each time that the left ventricle acts. There is no interruption

to the stream—there is a constant current of blood issuing from the artery; but it is thrown forward more forcibly at every contraction of the left ventricle of the heart. The quantity of blood that is lost in a given time, and the effect which the loss of blood will produce on the system, depend chiefly on the size of the vessel that is wounded. A complete division or large wound of the femoral or the radial artery, of the common carotid, or external or internal carotid, generally produces so great a loss of blood within so short a time, as to be suddenly, in fact almost immediately fatal. This observation you will not understand to be invariably and universally true; for the bleeding of a wounded vessel is in some measure modified by the nature of the division of the external parts. If the external wound be free, so as to allow an easy escape to the blood, then a wound of the vessels I have mentioned to you will be suddenly fatal; but if the external wound be small, so that the escape of blood is impeded, then the event may be different; and indeed I remember to have seen a case in which the brachial artery was cut across on the inside of the arm, at the same time a free division was made of the external parts, where there was a considerable loss of blood, so that the individual fainted; but the orifice of the artery was now tied, and the patient did not die from the bleeding.

Sometimes from a wound of one of these vessels the patient dies almost immediately; in other instances death does not take place quite so suddenly. Thus in an instance where the ligature came off the femoral artery after amputation, the gentleman in whom it occurred made a noise, which roused the nurse who was in his room, but by the time she had come to the side of the bed—he was dead: a profuse flow of blood had taken place, and the gentleman probably died in the course of one or two minutes. I remember an instance of a ligature giving way from the femoral artery in a lady in whom it had been applied for an aneurism, and in that instance death did not ensue till about an hour after the accident.

When an artery of the second order is wounded or divided—for instance, when either of the three arteries of the leg, the anterior or posterior tibial, or the peroneal; or any of the three arteries of the fore-arm, the radial, the ulnar, or interosseous; or any of the primary divisions of the external carotid—profuse hæmorrhage ensues, and a considerable quantity of blood is lost in a short time; but the individual faints, the bleeding stops, and death does not ensue immediately: the patient recovers, bleeding will come on again, and at a distant time repetition of bleeding may take place, and thus the patient may be destroyed ultimately by the repeated losses of blood.

When arteries of smaller size are divided, they bleed more or less freely at the time; but the hæmorrhage ceases spontaneously, and no further ill consequences ensue. It may sometimes happen that a wound of an artery of the second order, such as the radial, the ulnar, or the interosseal, or one of the arteries of the leg, may not be attended with an ultimately fatal effect, although no means are adopted to stop the hæmorrhage; the bleeding may stop, and the orifice of the artery may be obliterated by a natural process, without any recurrence of hæmorrhage. In the case of amputation of a limb, we see the remark that I have now made exemplified: we find it necessary to tie, perhaps, from one to six arteries—but the rest, which must of course be extremely numerous in a wound of this kind, cease bleeding of themselves, and no farther hæmorrhage takes place from them; they cease to bleed spontaneously—certain changes occur by which the hæmorrhage is arrested. Sometimes in the amputation of the thigh, we are only obliged to tie the femoral artery. I have known an amputation of the fore-arm and only one artery tied; and also only one tied in the amputation of the leg; the hæmorrhage from all the rest having been arrested by the spontaneous process.

You will, then, naturally inquire how it is that the bleeding of a wounded artery stops spontaneously? What is the course adopted by nature for arresting the flow of blood under these circumstances? The orifice of the divided vessel contracts, becomes smaller and smaller, and ultimately seems to close entirely. This natural contraction of the divided orifice of the artery is favoured by exposure to the air, or by the application of cold water by sponging; so that when we have exposed a wound, such as that made in removing the breast, or the wound of amputation, we shall, perhaps, find that the bleeding has entirely ceased. But when we bring the parts together, and more especially if they are covered by a considerable quantity of dressing or cloths, so as to produce heat, hæmorrhage will recur again from the vessels that had previously ceased to bleed. Then at the same time that the divided orifices of the vessels contract, the blood coagulates in their extremities, and a clot forms which resists the efflux of blood from the artery. A third circumstance has been mentioned as contributing to the natural suspension of hæmorrhage—namely, the retraction of the divided artery into the cellular sheath that surrounds it. This has been observed in experiments on animals; and I must state to you, that those changes on which the natural suspension of hæmorrhage depends, take place more powerfully in animals than they do in the human subject. The brachial, the femoral, and the common carotid arteries, may be divided in

the dog with impunity. Generally a considerable gush of blood takes place from these vessels; but the effusion of blood diminishes, then stops, the artery is closed, and the animal recovers. Under such circumstances, it is found that the ends of the divided vessels are retracted. You are aware that arteries are generally surrounded by a loose cellular texture, which connects them to the surrounding parts. This cellular texture is very loose, and admits the ends of the vessels. Now the vessels which are divided being withdrawn to a considerable distance from each other, under such circumstances, when blood is effused from a divided artery it passes into the cellular sheath, and coagulates. This forms a plug at the external orifice of the vessels, which assists in arresting the hæmorrhage.

Now it is difficult to say whether this process takes place in the smaller arteries; indeed I apprehend we may say clearly that the cessation of hæmorrhage does not, in them, depend upon this process; for you observe, in amputation, the flow of blood taking place from an artery in a considerable stream, which gradually diminishes in size till it stops, although the orifice of the artery is still in view, and therefore not at all retracted. We see, however, that where the arteries are seated in textures of a dense unyielding kind, they bleed more obstinately; the hæmorrhage is not stopped so quickly as when they are seated in textures of a looser sort, that admit of their retraction. Thus, in an operation on the female breast, when a part of the mammary gland is divided, we shall find that small vessels will continue obstinately bleeding in the dense texture of the gland, so that we are obliged to put a ligature to them. The dense, compact substance by which they are surrounded, prevents them from retracting. The same has been observed in the skin. You sometimes find a small artery in the texture of the skin continue bleeding, under circumstances where the arteries in a loose tissue would stop naturally. It is not impossible, therefore, that the retraction of the orifice of a wounded artery, in certain circumstances, may contribute to the suspension of hæmorrhage. Such are the circumstances which are considered to take place as the natural means of arresting bleeding. The contraction of the orifice, the coagulation of blood within it, and the retraction of the end of the vessel into the cellular sheath; and by means of this process, in many instances, hæmorrhage naturally stops, in complete division even of arteries of considerable magnitude.

I should, however, have observed to you, in respect to the natural means of stopping hæmorrhage, that those changes on which the effect depends are materially favoured by the state of faintness which is produced by

the loss of blood. The diminished force with which the blood is projected into the arteries, under the state of faintness, assists in the natural changes by which hæmorrhage is stopped. The coagulation of the blood particularly, in the orifice of a divided vessel, takes place more favourably under the reduced strength of the circulation. For this reason the condition of faintness may be considered as one of the natural means by which hæmorrhage is stopped; and hence, under ordinary circumstances, we should not be at all alarmed by its occurrence; we should not immediately attempt, as persons are apt to do, to raise the circulation by the administration of stimulants. Under such circumstances, we should rather regard the occurrence of fainting as part of the natural process by which the hæmorrhage is to be arrested.

The surgical means which are adopted to stop the flow of blood from divided arteries, may be arranged under three heads—*pressure, styptics, and ligatures.*

In the alarm which persons entertain, and almost instinctively feel, at the occurrence of serious hæmorrhage, those who are ignorant of anatomy and physiology seem to lose their presence of mind completely, and to neglect even the most obvious means for arresting the flow of blood. Although considerable vessels may have been divided, they might be stopped simply by the pressure of the finger; and yet persons see the blood flow from such a wound and do not take this obvious means of arresting it. Pressure with the point of the finger on the orifice of the divided vessel, or on the wound if it be small, or tying a handkerchief round the wounded part, with some tightness, will at all events arrest the blood for a time, till more effectual means can be adopted. Heretofore, when the application of ligatures was not understood, pressure was one of the principal methods, not merely as a *temporary* means, but for *permanently* arresting hæmorrhage. Sponge, or lint, or portions of linen, were laid upon the opening of a divided vessel, or wound; and these were bound firmly on the part by bandages; this pressure being continued until the wounded vessel was supposed to have united. It is very difficult to apply pressure to a wound of any considerable artery, so as to command the flow of blood through the vessel in such a way as is necessary, in order to accomplish the perfect cure of the wound. It is difficult to apply pressure in such a manner as to keep up permanently the degree of force on the wounded part necessary to accomplish this purpose. There are but few situations in which an artery is so situated, in respect to some bone or other firm part, as to admit of being effectually compressed; and if we use a degree of force in the application of bandages, sufficient to

bring the sides of the wounded artery together, we shall compress the whole of the limb in such a way as to endanger its mortification;—at all events, the application of pressure in this way irritates the wound, tends to produce inflammation in it, and will cause swelling of the limb generally. Thus it will bring on a state of the wound and of the limb in which the disposition to bleeding will be increased rather than diminished, while the slightest motion of the limb will be sufficient to disturb the pressure upon the wounded artery; so that, for these various reasons, pressure can by no means be trusted to as an effective method of arresting the flow of blood from an artery of considerable size. It is found, indeed, so very insecure, that it has generally been abandoned as a permanent means of arresting hæmorrhage. There may, perhaps, be some few instances in which pressure may be employed, but they are by no means frequent. In wounds of the temporal artery, more particularly in opening that vessel to take away blood, the artery being situated on a bone, it can be pretty effectually compressed; and in this case we find that pressure may answer the purpose. In a small wound of a large artery it is sometimes found that pressure will answer the desired purpose; and, as an example of this, I may mention the wound that is occasionally made in the brachial artery, in the operation of phlebotomy. I remember seeing an instance in which there was every reason to suppose that the brachial artery was punctured—that is, when the vein was wounded in bleeding, there was observed to come out from it a stream which was partly of a bright scarlet and partly of the dark colour of venous blood. The contrast in the colour of the two component parts of the stream was so great, that there could be no doubt upon the subject. However, in this instance, the quantity of blood that was desired was not obtained by the opening of the vein, even with this additional aperture of the artery; the blood stopped of itself, before as much had flowed as it was wished to take. A compress was placed upon the wound, and large portions of folded lint were applied, gradually increasing in size, so as to form a thick graduated compress over it. Another covering was laid along the trunk of the brachial artery, and this firmly bound on, a bandage being applied from the wrist upwards over the whole of the limb. This was the mode adopted for producing pressure in the instance that I have mentioned, and I may observe that it was completely effectual; no further loss of blood took place, nor did any aneurismal swelling occur. There may, therefore, be some few instances which will constitute exceptions to the general rule respecting the application of pressure as a means for arresting hæmorrhage from a wounded artery.

It has been said, that pressure may be employed where hæmorrhage takes place from a number of small vessels. I believe you find in general, under such circumstances, that the most advantageous mode of proceeding will be to expose the wound freely to the air, and sponge it with cold water. That generally succeeds in checking the flow of blood from small vessels. It has also been said, that pressure may be adopted where bleeding takes place from a surface generally. This, in fact, is hardly an example of arterial hæmorrhage; but it sometimes happens that the blood seems to flow almost generally from the whole of a denuded surface. This is what the French call *suintement de sang*. It is possible that there may be circumstances of that kind, under which pressure may be sufficient to restrain hæmorrhage, but you will immediately observe that these are different cases from those to which our present observations apply, viz. wounds of arteries.

I may state to you generally that pressure is neither a secure, nor in any respect an eligible means of restraining hæmorrhage when it proceeds from an arterial trunk of considerable size. As a temporary mode of arresting hæmorrhage, we may adopt pressure of the arterial trunk of a limb above the situation where the wound has been inflicted. Thus, if a wound be received in any part of the thigh, you press the femoral artery where it passes the crural arch of the groin. In the same way you employ pressure, with the tourniquet, to restrain hæmorrhage during amputation. This is a mode of stopping the flow of blood at the time, and I may mention to you that pressure employed in this way is a complete and effectual mode of checking hæmorrhage at the moment; and I state this the rather because a very ingenious and lively writer, and indeed a man of great talent, took much pains to convince the world that we could not, by pressure, command the flow of blood through a large artery. I allude to the late Mr. John Bell. His doctrine was, that we could not succeed in stopping bleeding by pressure upon an arterial trunk; and he says, that when a person presses on the groin, the blood flows through the artery just as if no pressure were made. How he came to this conclusion I am at a loss to understand, for I know this, that you may take the iliac artery between the finger and thumb, and command the flow of blood through it without great force; and in other circumstances it is well known (as in the amputation of the shoulder joint) we trust to the pressure on the subclavian artery to command the flow of blood, and we find the pressure perfectly effectual. In cases of wounds, either in the arm or leg, where bleeding has occurred, and we suspect it may occur again, we sometimes employ the

tourniquet, leaving it round the limb, to be tightened if bleeding come on. But the pressure thus applied can only be continued a short time. The tourniquet affects the circulation of the blood through the veins as well as arteries; it produces swelling of the limb; and if you continue it, the swelling so produced becomes painful—in fact it produces a state of the limb which will terminate in mortification. This kind of pressure, therefore, is only to be regarded as of temporary application.

Great confidence has been placed on the operation of substances called *styptics* in arresting bleeding. The exposure of a wound to the open air, and the application of cold to it by sponging with cold water, have a powerful influence in checking bleeding; and thus far these may be considered as styptics. But when we speak of styptics technically, we mean certain substances which are supposed to act in effecting a contraction of the orifices of the divided vessels, and thus stopping the flow of blood through them—substances of an astringent nature. Alum, and the sulphate of zinc, are, perhaps, those on which the most reliance can be placed. Oil of turpentine has been used for the same purpose, but probably there are no substances that are more certain, as styptics, than a saturated solution of alum, or the sulphate of zinc. We cannot, however, rely upon these, or any other styptics, for arresting the bleeding of an artery of considerable magnitude. They may check bleeding from small vessels, but it would be extremely unsafe to trust to them in a case where an artery of any magnitude, such as the radial, the ulnar, or, I might say, one of the digital arteries, was divided.

There are certain cases where divided vessels, in consequence of being deeply seated—so placed that we cannot get at them without cutting or interfering with parts of importance; there are, I say, certain cases of this kind in which we might depart from the general rule, and employ styptics; but then the employment of such means constitutes an exception from the general proceeding. On such an occasion I should, for my own part, be inclined to employ, in preference to other means, a saturated solution of alum; and the mode I should adopt would be to dip lint into the solution, sponging the wound clean, so that I might lay such lint upon the vessels that were bleeding, and then placing compresses externally; so that by means of a bandage over all, the wound might be subjected at once to the combined influence of the styptic and pressure. Under certain circumstances, perhaps this mode of proceeding may be eligible. I have known bleeding that has been troublesome stopped by the application of a piece of lint dipped in alum and Armenian bole, in equal parts, and finely powdered. Both these have been supposed to possess styptic properties; and when lint, dipped in them, has been bound upon the

part firmly, the blood will form an encrustation, or cake, over the surface, which is allowed to remain till the danger of hæmorrhage shall have gone by.

The only safe mode of proceeding, however, in order to restrain hæmorrhage of wounded arteries, is *the application of a ligature*. You will readily understand, that if the orifice of a divided artery be firmly tied, no blood can flow from it. The application of a ligature, therefore, is an effectual remedy for bleeding at the moment, and is followed by such changes in the state of the part as prevents any subsequent recurrence of hæmorrhage. The ligature which is applied separates of itself from the vessels at various periods of time, from four or five days to three or four weeks; and when we come to examine the end of the vessel on which the ligature has been applied, we find it is firmly closed; and, in fact, not only that the divided orifice is united, but that a portion of the tube, extending from the ligature up to the situation where the first branch is given off from the artery above the wound, is not only contracted but obliterated, and converted into a firm round substance. Such is the effect of the application of a ligature to an artery: so that you observe it is very effectual, not only as an immediate means of arresting hæmorrhage, but as also preventing the future recurrence of bleeding.

Now when we apply a ligature to an artery, supposing we employ one of the ordinary kind, and supposing we employ the degree of force that is commonly used in tightening them, the effect that we find produced is, that the two inner coats of the vessel, namely, the internal and middle coats, are divided or cut through. When you take off the ligature, after having drawn it in this way, and look at the vessel that it has been applied to, it appears as if you had cut through these coats with a knife. The external, or cellular coat being of a much tougher nature, is not divided by the application of the ligature; it is so firm in texture that it cannot be divided by any degree of force that you can apply. Such is the effect usually produced by tying a ligature round an artery.

[Mr. Lawrence here illustrated the immediate effects of the ligature by tying portions of various arteries, and exhibiting them.]

Thus you have an incised wound, if you may so call it, in the internal and middle coats of the vessel, and you have the edges of the wound kept in contact by the application of the ligature. The same circumstance takes place here as in the case of a wound of any other of the soft textures of the body; that is, coagulating lymph is effused; it becomes organized; and thus forms the medium of union by which the sides of the vessel are permanently held together and closed; it is, in fact, just the same process that takes place in a wound in any other soft part. The accomplishment of this process, in the case of a

wounded artery, is assisted by the coagulation of the blood in the extremity of the wounded vessel. The blood being at rest in the extremity of the vessel, coagulates, and the clot that is thus formed protects the extremity of the artery during the time that the effusion of coagulating lymph, and its subsequent organization, are going on. The clot of blood within the vessel prevents the effused coagulable lymph from being washed away; it prevents the union from being disturbed by the impetus of the circulation; it is, therefore, an auxiliary circumstance in the natural process on which the union of the divided artery depends, but it is not absolutely essential to it. We find that this coagulum extends up to where the first collateral branch is given off;—now it may happen that a vessel may be wounded or tied close to the origin of a branch; in that case no coagulum forms on the inside, and yet the vessel may be united. But it must be observed that the process of union is more precarious under such circumstances; it is more liable to be injured; and the instances in which secondary hæmorrhage takes place are more common.

When we see the mode in which this operation is to be effected, we can easily determine what kind of ligature should be employed in tying the arteries, and in what mode they should be used. Your object is of course to produce a small and clean cut of the internal and middle coats of the vessel. For this purpose we use a small, round, and firm ligature; for a ligature of that kind will produce a neat and clean cut. If you use a large ligature, you not only divide the internal and middle coats, but at the same time bruise them, and produce a considerable detachment of the external coat. You will find in the aorta which I tied with a rough piece of string just now, that the internal and middle coats are considerably separated from the external coat, and in fact, if you were to use a ligature of this kind, and put it on an artery, it is by no means impossible that you would divide the external coats also with it. The ligature, then, that you employ may be made of any substance you like, provided it possess these properties;—small in size, firm, and round. Silk ligatures, perhaps, will answer best, and usually that kind of silk which is called in the trade “dentists’ silk,” which is dense and firm, is preferred. If you use that, you can scarcely break it by any force you can employ with the fingers and thumbs.—[Mr. Lawrence here exhibited specimens of this kind of silk.]

Heretofore, before the process by which the suspension of hæmorrhage and the union of vessels was understood, it was very commonly recommended to employ large flat ligatures, and not to draw them very

tight, but merely to draw them so as to approximate the sides of the vessel without actually cutting them; indeed, it appears that the fact of the division of the internal and middle coats by ligature, was not noticed till the time of Desault. Dr. John Thompson, of Edinburgh, by whom this fact has been stated, mentions that he learnt it from Desault, and it was not generally known here till it was stated by him. You will observe, therefore, that the recommendation of the employment of large ligatures, and the injunction to draw them only so as to bring the sides of the vessels into contact without injuring the coats, proceeds on an ignorance of the process which takes place in arteries that have been tied.

I would not venture to say that an artery may not actually be cut through by a ligature drawn very tightly under certain circumstances. There are conditions of the arterial coats, especially in old persons, in which a deposition takes place,—a kind of cartilaginous substance is formed, or the artery becomes otherwise changed in such a way as to lose more or less of its natural elasticity and power of resistance. They become more brittle than natural, and it may be possible, therefore, that the arteries when they have thus been changed may, by the application of a large ligature drawn with great force, be cut through altogether. I have been speaking of instances in which we have occasion to employ ligatures in consequence of wounds, whether accidental or from operation, such as amputation, and I can venture to state that the smallest of the silk ligatures which I have shewn you, may be applied safely with the utmost degree of force that you can give it with your fingers, without the risk of cutting through the whole coats of the vessel, though you observe it will divide the internal and middle coats in the way that I have already pointed out.

The ligature should be applied to the arteries alone, and ought not to include any other part. If you include the surrounding parts, such as a nerve, a vein, or any other substance, you cannot calculate so confidently on producing the particular effect which you wish to produce on the artery; and if you include nerves or veins, you run the risk of serious ill consequences of another kind. It is desirable, therefore, in all cases to apply the ligature to the artery alone. This can easily be done in arteries of large size, because they are surrounded by a loose cellular sheath, which admits of their being drawn out from the surrounding parts by an ordinary pair of forceps, or an instrument called a *tenaculum*. You take hold of the end of the wounded vessel, draw it out, and apply the ligature immediately in contact with it, previously separating with your nail the vein or

nerve accompanying the artery. The ordinary forceps is used for this purpose, or the tenaculum, which is a pointed instrument, semicircular in shape,—or there are improvements of the tenaculum, one of which bears the name of Assalini's, which is so contrived as to admit of being employed to take up the arteries when you have not got an assistant: you take hold of the artery with the instrument perpendicularly, and it will keep its hold: there is a spring by which the branches of the instrument are kept together, and it will take up a very small vessel.—[Mr. Lawrence here shewed two instruments, one of the description just mentioned, and one where the branches were kept together by a slide, by which he said the orifice of the vessel might be securely held.]

With respect, then, to arteries of such a size as to admit of being drawn out, you use the forceps more especially for that purpose. In instances of arteries that run in the substance of muscles, or those that run in the texture of parts of a more solid kind, you find it necessary, with a sharp tenaculum, to transfix the orifice of the artery with some portion of the surrounding textures, including as little of them as possible in your ligature. When you have secured the bleeding arteries in this way, you generally cut off one end of the ligature close to the knot, leaving the other entire, and hanging out of the wound, and when by the process of separation the ligature has been detached, it falls off of itself. It is expedient generally to leave the ligature till it is thus naturally detached. In the case of an artery of large size, if you wished to draw the ligature off, and were to use force in pulling it away, you might disturb the end of the vessel, and thus interfere with the process going on for closing its orifice. The ulceration of the external coat of the artery, by which the ligature has been detached, takes place, as I mentioned to you, within various periods; it sometimes occurs in as short a period as five or six days, and sometimes it takes three weeks or more. If the separation of the ligature is delayed beyond that time, you may draw it slightly each day, till you find it gives way and comes off.

Attempts have been made to get rid of the irritation which the presence of a ligature in a wound creates, by cutting off both ends close to the knot; and I have done this in many instances after amputation, castration, removal of the breast, operations for aneurism, and various others, and I have not seen any ill consequences result from it. In many instances of that kind the wound unites, and the ligature seems to remain in the situation in which it was left, without producing irritation. In some cases, after a short time, a small point forms at the edge of the cicatrix, and a little matter escapes, and the ligature comes away. In every in-

stance where you see a reason to expect that the wound will not unite by adhesion, you can cut off the two ends of the ligature and leave the knot in the wound, because the knot then comes away in the suppuration. If the wound is likely to unite generally by adhesion, perhaps, on the whole, the best and the safest method is to cut off only one end of the ligature, and leave the other hanging out of the wound.

LECTURE XLII.

Application of Ligatures, continued—Armed Needle—Necessity of tying both ends of the Artery—Partial division of Arteries—Dif-fused False Aneurism—True Aneurism.

WE are sometimes obliged, gentlemen, to employ the *needle and ligature* in order to arrest arterial hæmorrhage. When the bleeding orifice of the vessel is deeply seated, or when, from other circumstances, we find great difficulty in securing the very orifice itself, in such cases we take a large curved needle, armed with a strong ligature, and pass it through, so as to include a considerable thickness of the parts embracing the vessels that are divided, and we then tie the whole together. Now this, which must be regarded as rather a coarse kind of proceeding, is only to be understood as an occasional expedient, where we cannot succeed in what should be our constant effort—that of securing the immediate orifice of the vessel that affords the hæmorrhage.

When an artery is divided, particularly in the extremities, it is necessary, or at all events it may be said to be proper, to tie both ends of the wounded vessel. Frequently we find that bleeding takes place, both from the extremity of the vessel which is nearest to the heart, and from that which is most remote. In the arm and forearm, where the arterial communications are particularly free, we find this take place very frequently, and also in the scalp: when the temporal, or occipital artery is wounded, we shall find the vessel bleed as freely from the orifice most remote from the heart, as it does from that which is nearest it. Under these circumstances, it is a matter of obvious necessity to tie both orifices of the wounded vessel. But it may be laid down, as a *general rule*, that you ought to do this even although no bleeding should take place, from the farthest opening at the time that you apply the ligature; for although no hæmorrhage may be present at that time, yet it not uncommonly happens, when the circulation becomes powerful, that bleeding does come on afterwards, and you may have, from the inferior or more remote orifice of the vessel, subsequent hæmorrhage, that may even prove fatal.

I remember an instance of a person brought

into this hospital, many years ago, who had received a very considerable and deep wound on the inside of the arm, a little above the elbow. This had occurred in an affray in the street. Profuse bleeding took place, and he was carried into a neighbouring house, where a surgeon, who was near the spot, came to his assistance, tied the artery, and then sent him to this hospital. When he arrived here, he was cold, and almost senseless; extremely reduced by the loss of blood; and a ligature was observed in the wound. No bleeding at that time took place; and it was necessary to give him a little wine, and employ other means to restore the circulation. The edges of the wound were brought together as a simple incision would be, and the patient soon recovered from the immediate effects of the loss of blood. The wound seemed to be uniting very favourably, and all the circumstances appeared quite as one could wish, when, on the sixth day after admission into the hospital, profuse hæmorrhage took place. This happened during the night, and the bleeding was not discovered till the morning, when it was found that he had lost a very large quantity of blood; so much so, indeed, that it had soaked through the bed and bedding, and was dropping on the floor of the ward. When the house-surgeon saw the patient in the morning, as soon as the hæmorrhage was discovered, he opened the wound, and found no bleeding whatever. In the course of this examination, the ligature, which had been on some vessel in the first instance, came away, but no bleeding then occurred, and the wound was closed. On the following day, however, a profuse hæmorrhage came on again, and under this the patient died. I examined the body myself; (I must observe that the patient was not under my care, it was long before I was surgeon to the hospital;) I found a deep wound, that extended to the bone, and had divided the brachial artery, with the accompanying veins and nerves. The extremity nearest to the heart, on which the ligature had been placed, was closed. The orifice was filled by a coagulum, so that no blood could have come from it; but the inferior extremity of the artery was open, and no doubt, in this case, the patient bled to death from the lower orifice of the wounded vessel.

The observations that I have now made to you relate to the course which you are to pursue in treating wounds of the arteries when the trunk is completely divided transversely; but there may be an imperfect transverse division of the artery, or the artery may be wounded longitudinally, or it may be wounded obliquely. In any of these cases you must follow the course that I have already mentioned, that is, you must tie the artery above and below the situation of the

wound. This plan of tying the artery is still more necessary in these partial wounds than in the complete division of the tube. The partially wounded artery is placed under less favourable circumstances, as regards the natural cessation of hæmorrhage, than a completely divided vessel. A partially divided artery cannot retract into the sheath; the orifice of a partially divided artery does not contract towards a central point, so as to close it up. Thus we find, that the contraction and retraction of the arteries—the two circumstances principally conducing to the natural cessation of hæmorrhage, are both wanting. It is true that these partial wounds of an arterial tube, like a complete division, may, in some instances, admit of a spontaneous cure, particularly if the external wound be small. If effective compression be made upon the arterial trunk; if the limb be kept completely at rest; if the patient should altogether remain very quiet; and if such a course generally should be pursued as is calculated to diminish the force of the circulation, under such circumstances either entire or partial wounds of arterial tubes, even of considerable size, may be spontaneously cured; but such is an exception from the ordinary course, and we cannot calculate upon it as a regular occurrence; nor should the fact that such cures do occasionally happen, lead us to neglect the general rule of tying the wounded artery, that being the only mode by which we can place the patient in safety. In some instances, where a puncture of an artery has been made, and been very small, (such, for example, as a wound in the brachial artery, which occurs in bleeding,) by the employment of pressure, and other means, the wound in the artery closes without the tube being obliterated, and it is healed much like the wounds which unite by adhesion in other textures of the body. But these are rare occurrences; and, generally speaking, whenever spontaneous cure does take place in the partial wounds of arterial tubes, it involves the obliteration of the vessel in the situation where the wound has been received.

The observations that I have now made to you relate to those wounds of arteries which are accompanied by free external wounds, where there is complete exposure, so that we can find out the bleeding vessel, and do what we please with respect to it. But in many instances arteries are wounded by punctures. You have a wound of a considerable artery where the external orifice is small, and seated at a considerable distance from the division in the blood-vessel. Under such circumstances, a profuse rush of blood takes place at the time that the injury is received, supposing that a large artery be wounded; but as the blood escapes more slowly in proportion as the circulation becomes enfeebled, it at last coagulates in the

track of the wound, and thus prevents further hæmorrhage. The patient faints, and a much less quantity of blood is lost than would have been the case had there been a free external aperture in the neighbourhood of the wound in the artery.

In this way you may have the femoral, or even the axillary artery, wounded in any part of their course, and yet the patient may not bleed to death. The blood does not escape freely through the wound; and thus the hæmorrhage is stopped before such a quantity is lost as produces a fatal result. In the reduced state of the circulation which takes place, ending in fainting, a coagulum may probably form in the orifice of the wounded vessel, and this stops the bleeding for a time. The patient, however, recovers; the circulation becomes nearly natural again; the coagulum is forced out, and the bleeding may return after one, two, or more days. Profuse hæmorrhage may come on again, which hæmorrhage is repeated from time to time; and in the end, either the surgeon cuts down, and secures the wounded vessel, or the patient dies from these repeated losses of blood.

Sometimes the bleeding from the wounded artery is checked so long, either by a coagulum forming in the tube, or in the track of the wound, that the external opening absolutely becomes quite united and healed; yet the artery, although it does not bleed externally, bleeds internally. Blood is injected into the cellular substance immediately surrounding the vessels and their sheaths; it is effused into the cellular substance between the muscles of the neighbouring parts; and thus tumefaction arises, first, in the neighbourhood of the wounded vessel, and then it extends, more or less, to the soft parts around it, often increasing the size of the limb to a very considerable magnitude. In this latter case, the swelling, I should observe, particularly in the immediate neighbourhood of the artery, pulsates. This is the kind of case which has technically been called a *diffused, false aneurism*. The tumour that takes place has this character, in common with aneurism—swelling, with pulsation. But the swelling is not circumscribed; it is made up of an irregular injection of blood into the cellular texture, immediately surrounding the artery, and which extends to the various contiguous parts. Thus it is said to be a *diffused*, in contra-distinction to a *circumscribed* false aneurism. In this way you may find that nearly the whole of the cellular texture of the limb may become distended with blood injected into it from the wounded artery; and you may have tumefaction which occupies nearly the whole of the member.

The course of proceeding in either of these cases is just the same as that which I mentioned to you as fit to be adopted in cases of

complete transverse division of the artery in an open wound. You must find out the wound in the artery, and secure it by a ligature; and unless you do this, the patient continues in danger of his life, and the surgeon must be kept in a state of the greatest anxiety and alarm. It is important that you should do this as early as possible; for if hæmorrhage takes place from the wound, and if it still remains open, the repetition of this hæmorrhage in cases of important arteries, such as the femoral, though it may be of short duration, is attended with imminent risk to the life of the patient; and I have just mentioned to you a case where a patient bled to death even from the inferior orifice of the brachial artery. If it is a case of diffused false aneurism, the longer you delay the operation the more difficult it becomes; for as the swelling becomes more considerable, the relative position of the parts is more difficult to ascertain;—you have a greater depth of parts to divide before you arrive at the wounded vessel, and you perform the operation altogether under increased difficulties of every kind. There is another source of difficulty in these cases: in order to protect the patient from sudden death, it is common to put a tourniquet upon the upper part of the wounded limb: now the application of this instrument is attended with excessive pain, and a general swelling of the limb below the part where it is placed. Thus all the circumstances that take place increase the difficulty of the operation; and, in fact, these difficulties become more and more considerable the longer the operation is delayed. The wisest plan would be, to cut down upon and take up the vessel immediately after the accident has taken place, if it be practicable, for then the parts are free from effusion and swelling, so that you have all the natural guides to direct you in seeking for the artery.

The operation of cutting down upon and securing the artery, in some of these cases is a very serious, and indeed a very difficult one; so that it is necessary for you to be quite clear respecting the nature of the case before you commence an undertaking of this kind. Perhaps you have not seen the patient immediately at the time that the wound has been received—you do not know the circumstances that have occurred, and you must be satisfied to trust in a great measure to the report of others, in order to guide your judgment upon various important points. In the first place, you would have reason to suppose that an important artery has been wounded if profuse hæmorrhage took place immediately after the accident, and particularly if you can ascertain that it has been arterial;—in the next place, if there be a recurrence of free hæmorrhage some time after—if both these circumstances have taken place in the case, there can be no

doubt that an artery, and that, too, of considerable magnitude, must have been wounded. You generally derive some information respecting the probable nature of the wound by observing the state of arterial pulsation in the vessels of the limb beyond the situation of the injury. If the main artery should have been seriously wounded, you will probably find that the pulsation is either suspended, or at all events materially altered, in the vessels that are situated beyond the injured part.

Then, having ascertained these points—having established your diagnosis so far as circumstances enable you to do this, and having come to the conclusion that an artery is wounded, and that it is necessary to take it up—you proceed to perform the operation, first placing a tourniquet on the main arterial trunk, above the situation of the wound, or having it compressed by an assistant. You observe, of course, the situation of the external wound, and ascertain, if you possibly can, the direction which the instrument that inflicted the injury has taken. Thus you may be led to infer with some accuracy the situation in which the artery has been incised. You must then make a free incision over that situation, and you will find much advantage in making a large opening in such a case; for you generally want much room where the arteries that are wounded lie deep, and unless you make an incision of considerable magnitude, you have to enlarge it afterwards, or are embarrassed in finding out the artery, in consequence of the opening being too small. When you have made the incision—supposing it to be a case of diffused false aneurism—you find, when you cut into the tumor, that you come to a quantity of recently coagulated blood; and when you have taken that out, and cleansed the wound by means of a sponge, you very commonly find that the wounded artery is dissected already for you, by the injection of blood into the cellular texture: you see the artery lying before you, and are able to discern the opening—that is, as soon as you loosen the tourniquet, or relax the compression on the arterial trunk: you have then no difficulty in being able to tie the vessel in the situation of the wound.

About a year and a half ago a patient was brought to this hospital who had received a wound of the femoral artery in the lower part of the limb: I think it was inflicted by a knife, which opened the artery, where it passes through the tendon of the triceps. The patient lost a large quantity of blood, and considerable hæmorrhage took place three or four hours after the receipt of the injury. It was found necessary to make an opening in the situation of the wound, and take up the artery. The place where the vessel was wounded here was deep, and there was a great deal of difficulty

in finding it; however the wound was dilated, and the vessel laid bare, when an opening was found in the artery about three-quarters of an inch in length—it seemed to have been slit longitudinally. A ligature was placed on the artery above the wound, and when it was so placed, and the tourniquet was loosened, the artery bled very freely from the lower orifice. Of course from that circumstance—though even otherwise it would have been deemed necessary—but that circumstance clearly shewed the necessity of tying the lower orifice of the artery, which was secured accordingly, and the patient did very well.

I also remember the case of a boy brought to the hospital a great many years ago, who had had a knife fall obliquely on the upper part of his thigh. A large quantity of blood flowed from the wound at the time of the accident, but he fainted, when the hæmorrhage stopped, and the wound was brought together. In that case a swelling formed on the anterior and upper part of the limb; it was a case, in fact, of diffused false aneurism. The wound here was seated so high up that the tourniquet could not be applied, and it was necessary to compress the artery where it passed over the bone. In laying bare the artery, I cut through the skin, and took out the coagulum: now in this case, as I have already mentioned, the artery was found very free, insulated by the injection of blood, so that it was easily taken up, and two ligatures were applied. Such is the course you are to pursue in cases of this kind.

In some of these injuries, the exact situation of the wound, the vessel itself, in fact, that is wounded, is uncertain. The vessel may, perhaps, be wounded in a part of the limb where it is very deeply seated, and the surgeon experiences considerable difficulty in exposing and securing it. Hence he is led to inquire whether the end might not be equally answered by taking up the main artery of the limb at a higher point, in some situation where it is more easily accessible. Supposing the vessel is wounded in the ham, for instance, it might be supposed that the femoral artery might be easily tied in the situation where it is ordinarily operated on, for popliteal aneurism. Now when the artery is tied above the situation of the wound, the hæmorrhage from the wound below is stopped for the time, and in some instances it is stopped permanently; but in the majority of cases, although it is stopped for a time, it recurs after a longer or shorter interval. Thus, at last, the necessity arises for securing the vessel in the situation where it has actually been wounded.

I remember an instance which occurred in this hospital a great many years ago, illustrating this point. A woman received a wound from a piece of glass, about the middle of the fore arm. A pointed piece of

glass struck her on the fore arm, penetrated to an uncertain depth, and produced a wound, from which free bleeding took place at the time of the accident. The wound was brought together, however, and a compress applied, and the parts seemed to heal over. There was a kind of scab formed, and this scab had given way twice, and profuse bleeding had taken place, which, as far as could be ascertained, was of an arterial character on each of these occasions. This woman came to the hospital at the end of three weeks from the accident, and the above was the account she gave of herself. Profuse bleeding had taken place at the time of the accident, and two recurrences of such bleeding, on the scab of the wound giving way. When she came to the hospital, there was a considerable swelling upon the anterior part of the fore arm, which pulsated in the situation where the wound took place. After she had been a short time in the hospital, the wound gave way again, and another free arterial hæmorrhage took place from it. On considering the circumstances of this case, it seemed very doubtful what vessel was divided, whether it was the radial or the interosseal. It was quite uncertain how far the glass had penetrated, and it was, therefore, judged proper to try the effect of tying the brachial artery. This was done with two ligatures, and was followed by a cessation of the hæmorrhage at the time, but soon after the pulse could be felt at the wrist, and a slight pulsation occurred in the situation of the tumor. The patient was kept quite quiet, evaporating cloths were laid on the arm, and all the means adopted which were calculated to lessen the force of the circulation: however, on the eighth day after the ligature was placed on the brachial artery, the original wound again gave way, and free arterial hæmorrhage took place from it. This shewed the necessity of cutting down in the situation of the wound, and securing the bleeding vessel. The tourniquet was applied, an incision was made, and then the radial artery was seen with an opening involving about half its circumference. The tourniquet was slackened, and the blood flowed freely from both extremities,—from that portion nearest to the heart, and from that most remote. A ligature was applied above and below the wound, the artery was cut across between them, and the case terminated favourable.

A soldier received a wound in the calf of the leg, at the battle of Albuera. The ball went in at the posterior part of the calf, and came out in front, on the other side of the tibia, having passed between the bones. Very free bleeding took place at the time of the accident. This occurred on the 16th of May, and on the 15th of June hæmorrhage to a very considerable extent, and of arterial character, took place from the wound; and

as the precise situation of the wound in the artery was quite doubtful, and as the bullet passed through the thick part of the calf of the leg, the surgeon took up the femoral artery just above where it passes through the tendon of the triceps. This arrested the hæmorrhage at the time, but, about three or four days after, bleeding again came on from the wound, and it was deemed necessary to amputate the limb. It was found on examination that the anterior tibial artery was the one injured by the bullet.

These facts shew you that you cannot trust, in the wounds of arteries, to ligatures of the arterial trunk above the injury: the freedom of the collateral circulation is so great in all parts of the body, that you find hæmorrhage will take place from the wound of an artery, although you may have tied the main trunk higher up. Hence it is very necessary, in all such cases, if possible, to cut down and secure the wounded artery in the situation where the injury has been received.

Aneurism.

I next proceed to speak to you of *aneurisms*. An aneurism is a tumor usually attended with pulsation, formed by a general or partial dilatation of an artery, or in consequence of a wound, rupture, or ulceration of some part of the coats of an artery. The tumor which accompanies an aneurism is hollow, and filled, during life, with blood either in a fluid or coagulated state. The tumor is continuous with the artery on which it is formed; indeed the sides of the tumor itself consist either entirely, or at all events in part, of an expansion or continuation of the proper tunics of the artery. The hollow tumor, then, thus formed and thus filled with blood, constitutes what we call the sac of the aneurism; in fact, it is the aneurism itself. But we speak frequently of an *aneurismal tumor*, or an *aneurismal sac*—the sac meaning that portion of the swelling which is formed either of the dilated or ruptured portion of the tunics of an artery. Then there is a free communication between the tube of the affected artery and the aneurismal sac; and that communication either consists of a single opening, which may be circular or oval, or slit-like, or it may consist of two openings—that is, the artery proceeding from the heart opens into the aneurismal bag at one point, and at some distance there is an opening leading to the continuation of the trunk further on in the limb.

[Mr. Lawrence here presented two specimens, remarking]—Here is an aneurism seated on an artery where you observe there is a single aperture: this is the arterial tube cut open; this is the aneurismal sac; and you see a single opening, measuring

about one inch in diameter—it is of an oval shape. Here is another aneurism, where there are two openings; this is an aneurism of the subclavian and axillary arteries. You observe there is a considerable interval between the two openings.]

The general doctrine respecting aneurisms has been, that there are two kinds of the disease; one consisting of an uniform dilatation of the coats of an artery, and the other of a partial enlargement of these coats, or rather a rupture or giving way of the coats, so that the aneurismal sac is formed only in part by the tunics, the rest being composed of the cellular sheath of the artery or other surrounding parts. These two kinds of aneurism are distinguished by the terms *true*—and *false*, or *spurious*; true aneurism having been considered to be that which is composed of the uniform and general dilatation of the coats of an artery; false or spurious aneurism, that which is produced by the partial giving way of the coats.

The propriety of this ancient division of aneurism has been called in question by Scarpa, who has endeavoured to shew that there is in fact no such thing as true aneurism, but that all aneurisms are false—that is, that they consist in a partial ulceration or giving way of the coats of an artery, in consequence of which the blood comes into contact with the cellular sheath of the vessel, distends it, till, by its enlargement and ultimate giving way, the blood comes in contact with the various surrounding parts, which then compose the aneurismal sac. The accurate investigation into the nature of the formation of aneurisms which has followed, in consequence of the promulgation of this opinion of Scarpa, has tended to shew that the ancient opinion is the correct one—namely, that there is a general dilatation of the arterial tube, or true aneurism; and also that certainly a great proportion of cases consist of what, according to the ancient division, would be called false or spurious aneurism—that is, aneurism formed by ulceration and the partial giving way of some part of the arterial tunics. A true aneurism is, in fact, a dilated artery; and such aneurisms are chiefly seen in large vessels, like the aorta. They may take place to a considerable extent there, as this preparation [exhibiting it] evinces. This is a large aneurismal sac, measuring some inches in diameter, and it is composed of a general dilatation of the artery; so that, if you examine any part of the sac, you find it consists of three proper tunics—the external or fibrous, the middle and the internal. In those cases where the arteries are thus dilated, we find that the arterial tunics are considerably diseased—that is, they become thickened, and on the internal coats are cartilaginous and osseous

depositions; so that it is not merely a dilatation, but a dilatation of the vessel accompanied with important diseased alteration of structure.

[Mr. Lawrence here presented various preparations in illustration.]

The great majority of aneurisms, however, and particularly those that we have to operate on—that is, those seated in arteries of the second magnitude, as in the primary branches of the aorta—are aneurisms of the false or spurious kind, according to the ancient division. Scarpa states that they are formed by a partial ulceration of the internal and middle tunics of arteries; that these become destroyed at a certain point; that the blood passes through the opening thus made, and distends the external or cellular coat of the artery into the aneurismal swelling. [Mr. Lawrence here showed a specimen.] This seems to exhibit the process. There is here a small swelling formed upon the abdominal aorta. There is a little round opening, shewing where the coats had given way, and through which the blood had passed, distending the external coat of the vessel. This specimen seems to correspond pretty nearly with the description Scarpa has given of aneurism in the early stage. It is very uncommon to meet with an example illustrating this early period of the formation of aneurism, and I must observe that this is a part of the doctrine of Scarpa which is defective in evidence. We have abundant examples illustrating the progress of these aneurisms when they have attained some size, but Scarpa does not give any cases, or representations by figures, of the incipient stage of such affections—that is, in which the internal and middle coats are ulcerated, and the blood is making its way to the external coat, so as to form aneurism. That part of his description cannot be considered as made out satisfactorily. We know, on the contrary, that the aneurism of which I am speaking may form by a partial dilatation, including all the three coats of the vessel. We meet, not uncommonly, with such partial dilatation of the arterial tube; and in the small aneurism thus constituted we can trace all the three component parts of an artery, but we can see no such actual ulceration or giving way of the middle and internal tunics; on the contrary, we observe at the commencement of the affection an uniform dilatation of the three arterial tunics. When this dilatation has gone to a certain point, the internal and middle coats of the artery do not seem to admit of farther extension. They then give way by ulceration, and thus the cellular sheath of the artery becomes exposed, so that the blood comes in contact with it, and thus it forms a part of the aneurismal swelling. This distends and gives way to a certain extent; and then, in proportion as the aneu-

rism increases, the neighbouring blood-vessels or tendons, or nerves, or muscles, become involved in the progress of the tumor, and form part of it. Thus, in the case of spurious aneurism, the tumor may rather be said to be a swelling formed upon an artery than to be a swelling of an artery. We find the artery, in three-fourths of the circumference, quite entire, but in the remaining part there is a portion which has given way, and the opening communicates with the sac of the tumor.

The specimen which I have just exhibited illustrates the mode of formation of an aneurismal swelling of this kind. If you look minutely at it, you see a giving way or opening of the vessel, and that the tumor is formed round that aperture like a kind of lump or knot. It is by no means a general dilatation of the artery; you see that it is a swelling formed on one side of the vessel.

[Mr. Lawrence then presented a drawing from the preparation he had just exhibited. The circumstance, he said, was perhaps rendered a little more clear in the delineation than it could be in the preparation. In the plate was seen a small opening, and the swelling was obviously a tumor formed upon the artery at one spot, the main tube of the artery not being interrupted by it; such being the nature and appearance of false aneurism formed upon a large arterial trunk. A second plate represented a small tumor of the descending aorta, somewhat analogous to the preparation he had shewn; it formed a swelling seated on the anterior part of the vessel—an appearance, Mr. Lawrence remarked, very different from the general enlargement of the tube, observed in true aneurism. A third plate represented a view of an incipient dilatation—the early stage of true aneurism.]

Now you observe, from this view of the sac, that an aneurism is differently formed in the different species of the complaint. In the true aneurism, the sac of the aneurism is, in fact, composed of the regular arterial tunics, just the same as make up the tube in its healthy state. But in spurious aneurism you find you can only trace the arterial tunics from the healthy tube through the opening into the beginning of the sac; you find for the space of an inch, or an inch and a half from the healthy artery, there is a smooth, internal lining on the inside of the sac, but then you come to a point where the internal coat appears with a ragged edge, and from that point the sac of the aneurism is formed by the consolidation of the cellular membrane of the parts in which it is developed; the muscles, or tendons, or nerves, being implicated, and forming a part of the sac. Indeed, the cellular membrane that becomes successively involved in the aneurismal swelling undergoes the same kind of change which the cellular membrane does

in the neighbourhood of phlegmonous inflammation of any kind. Adhesive inflammation takes place, by which it is consolidated and rendered firm, so that it is converted into a dense texture, which confines the blood, and forms a kind of regular membrane, and this same consolidation extends to the muscles and nerves, and other parts that are accidentally included in the progress of the aneurismal tumor.

There are hardly any limits to the swelling in a case of spurious aneurism, because if there is an abundance of cellular substance and of the surrounding parts for the aneurism to extend itself in, it goes on increasing in size. When an aneurism comes in contact with bone, it produces absorption of that bone. Thus in the case of an aneurism seated in the aorta, when it approaches towards the parietes of the chest, it makes its way through the sternum, through the ribs, and even through the vertebrae.

[Mr. Lawrence here presented a preparation, and said,—This is the case of aneurism of the aorta, such as I am speaking of; it has proceeded to the sternum, and come through it. The cyst is composed, not of the arterial tunics, but is made up in the way that I have described to you, of a consolidation of the cellular substance of the parts into which the aneurismal tumor has extended.]

In the same way you may have an aneurism of the descending aorta penetrating through the ribs behind to the back, so that there is hardly any limit in such circumstances to the possible increase in the size of the aneurism. The dimensions to which these spurious aneurisms may attain, and the length of time that will occur before they give way, depends therefore upon the nature of the parts in which they are formed, and upon the quantity of cellular substance that is seated between the artery and the external surface, as well as on the greater or less resistance that is presented to its increase.

An aneurism will sometimes take place in the aorta, in that part of the vessel which is covered by the pericardium. There is merely the pericardium, externally, and the cellular substance which connects the pericardium to the tube. Aneurisms here generally burst when they have attained the size of a hazel-nut, or at the largest, a walnut; but when they are seated in the lower part of the descending aorta, you may have an aneurismal tumor formed capable of containing two, three, or more pints of blood.

Inasmuch as the blood which is seated in an aneurismal tumor is out of the direct course of circulation—inasmuch as it is not constantly impelled through the vessels in the way that blood naturally is, it has a tendency to coagulate in the aneurismal sac. We find, in fact, that when the aneurism has attained even a moderate size, the

fibrin of the blood is separated, and forms a thin stratum, lining its internal surface. The fibrin is separated, that is, the stratum that lines the aneurismal sac is of a greyish or light brown colour, consisting of part of the blood without the red particles. The fibrin is deposited in successive strata one after another, and thus the cavity of the aneurism becomes lined by numerous successive layers of coagulum, adhering in the first instance to the sac, and then successively to each other. This is called a *laminated coagulum*, because when you open the aneurismal tumor after death, you find besides this that the rest of the cavity of the aneurism contains a large quantity of recently-clotted blood—that is, the blood which may have happened to be in the aneurismal tumor at the time of death coagulates, and appears like a recent clot. But that is quite a distinct matter from the tough, light yellow, or brown stratum of fibrin which lines the sac of the aneurism, and closely adheres to its surface.—[Mr. Lawrence illustrated these facts by various preparations, in one of which the coagulum when it was cut through resembled layers of paper.]

The recently coagulated blood comes away easily—we wash it out of the sac; but these lamina remain firmly adherent to the sac, and we cannot separate them unless we use considerable force. I am surprised to find that sometimes these laminated coagulæ are spoken of as if they were an actual deposition of lymph: there is, in my opinion, not the slightest ground for such representation. It seems to me perfectly clear, that these are separations of the fibrin taking place from the blood that circulates through the arterial tube gaining admission to the sac of the aneurism through the aperture in the sides of the vessel;—they are not organized, although they are tolerably firm, and adhere to the side of the aneurismal sac. There is no pretence whatever for saying that they are organized; they receive no vessels, and they do not seem at all to admit of organization.

Now the natural progress of an aneurismal tumor is to become larger and larger; at the same time it gradually advances towards the surface of the body. Like a collection of matter, or like a tumor of any kind in the cellular substance, it elevates the skin and forms an external tumor, and the side of the cavity becomes thinner and thinner, till it bursts. Although coagulum may be deposited in other situations, we do not find that it is formed at that part where the aneurismal tumor is advancing to the surface. When the integument has become very thin, the aneurism ultimately gives way; and this occurs in a different manner under different circumstances. Very commonly the integument is rendered so very thin that it is deprived of vitality, and a slough forms at the most prominent part of

the skin; and when the slough separates, the blood in the aneurismal sac escapes, and free hæmorrhage takes place. The patient either dies now, or the hæmorrhage stops for a short time, but is soon repeated, and ultimately proves fatal. Sometimes the integument, instead of sloughing, ulcerates; sometimes, particularly in cases of internal aneurism, it gives way by actual rupture, or bursting. I have alluded to the cases of small aneurisms forming on the aorta, within the covering of the pericardium: these, when I have seen them, have given way by rupture; there has been an actual rent or breach in them, found on examination after death, just as if you had lacerated the part by force; and in some other instances of internal aneurism I have seen the same thing.

Now sometimes there is a bursting of the sac into the cellular substance, by which an aneurism that in the first instance has been circumscribed becomes diffused. The aneurismal tumor increases in the way that I have described for a certain time, slowly augmenting in size; but the patient is aware suddenly—perhaps in consequence of some effort—of a rupture, as of something giving way; at the same time there is an immense increase in the size of the tumor. I have seen this in an aneurism seated at the bend of the thigh in the groin, and in the axilla. I have seen it also occurring in the ham; and when such an aneurism has been examined, that portion of the aneurismal tumor immediately in contact with the artery has been composed of a continuation of the arterial tunics, and the rest has consisted of the condensed cellular membrane, and other surrounding parts. Under other circumstances it has generally been made up of vessels, nerves, and other parts not much altered. The sac has burst, and thus the surrounding parts receive the blood from it: a kind of internal bursting of aneurism, by which, in some instances, a great increase takes place in the size of the external tumor.

LECTURE XLIII.

History of Aneurism—(continued).—Spontaneous Cure—Operation.

[MR. LAWRENCE, at the commencement of this lecture, presented a specimen of an aneurism of the aorta seated just above the semilunar valves; and remarked, that when aneurisms occur in this part of the aorta, they cannot increase much, as there is but little cellular membrane, and merely the serous membrane covering them; so that they burst at an early period. The specimen was such an aneurism, about the size of a small orange, which had burst into the pericardium.]

The lecturer then resumed:—I described

to you, gentlemen, in the last lecture, the origin and increase of aneurisms, and their progress towards a fatal termination by bursting. Now aneurisms do not always end thus unfavourably; they admit of cure by natural processes and by artificial means. The deposition of the fibrin of the blood, which I have already had occasion to advert to, proceeds sometimes until the cavity of the aneurism is filled up, so that the tumor is converted into a solid swelling, and the passage of the blood into it is completely obstructed. Thus the impetus of the blood, entering the aneurism from the artery, is entirely prevented, and the process by which the increase of the aneurismal tumor should be continued, is put a stop to. Under such circumstances the sac contracts, the fibrin that has been deposited in it becomes absorbed, and this process goes on until the coagulum by which the sac has been obstructed is entirely removed; the tumor becomes solidified, and the artery itself is reduced to an impervious fibrous cord. In this way the aneurism terminates, by the natural obliteration of that part of the artery which has been the seat of disease. You have already seen that the tumor that constitutes the aneurism is seated upon the trunk of the artery. Now if the situation of the parts behind the arterial trunk be such as to limit and prevent the natural extension of the tumor externally, the tumor must be increased either in a direction downwards or upwards, so that a considerable portion of the tumor will lie actually upon the arterial trunk, either upon that portion of the trunk which is immediately above the origin of the aneurism or that which is below it. Under such circumstances, if the external parts continue to press upon the tumor, so as to prevent its extension externally, the tumor compresses forcibly the trunk of the artery. Thus the pressure of the aneurism itself may bring together and keep in contact the sides of the artery either above or below the original seat of disease, and thus lead to the obliteration of the vessel.

I remember examining a patient in this hospital who had died of an aneurism, or rather in consequence of an aneurism, seated in the external iliac and femoral arteries. In that instance, the pressure of the tumor had produced a consolidation of the lower orifice of the artery, and for two or three inches of the arterial tube immediately contiguous to it. It must be obvious to you, that if the tumor had pressed upon the superior instead of the inferior orifice of the artery, the occurrence of the same consolidation would have been a natural cure for the aneurism.

There is a third way in which aneurisms are spontaneously cured—that is, by the occurrence of inflammation and sloughing in

the aneurismal sac. I have already mentioned to you that the most prominent point of the aneurismal tumor will slough when the integument has become very thin, and in that way the aneurism breaks externally. But I am not now speaking of a slight partial sloughing, such as that, but of a general inflammation of the whole aneurismal sac, ending in the sloughing of a considerable portion of it. Such an inflammation is attended with a high degree of local disturbance, great redness, violent pain and heat, with a corresponding febrile disturbance of the system. Matter will form in the sac and the integuments round it, and the external covering of the sac will slough; and while this process is going on, the blood coagulates in the aneurism, and generally also in that part of the arterial trunk which communicates with the sac. You might at first expect that sloughing of the aneurismal sac would lead to fatal hæmorrhage, when it gives way; but you will remember that in this case the same circumstance occurs as in the sloughing of a considerable portion of the extremity of the body; in fact, before the part actually perishes, there is a coagulum of blood formed in the vessels, extending considerably higher than the actual seat of the mortification. The same occurrence in the aneurismal sac has the salutary effect, not only of preventing hæmorrhage when the slough gives way, but, if the strength of the patient should be sufficient to support him through the general disturbance that attends the process, it will lead to his final restoration.

There are three ways, then, in which aneurism may be cured spontaneously, by the changes that take place independently of any interference of medical or surgical treatment. The increase of the deposition of fibrin in the aneurismal sac, leading to its gradual filling up and obstruction—the obliteration by pressure of the extremity of the artery communicating with it;—the inflammation and sloughing of the aneurismal sac, and the coagulation of blood in the extremities of the arterial trunk, leading to its final obliteration.

When aneurisms are cured by any of these natural processes, the arterial trunk in which the disease has been situated is found, on examination after death, to be obliterated: that is, the trunk is filled up, it is converted into a solid fibrous cord, the artery is no longer pervious, and this process of obliteration extends upwards and downwards in the trunk as high as the nearest collateral branches, sometimes occupying the space of two or more inches.

I remember the case of a patient in this hospital, a great many years ago, who had a large aneurism of the axillary artery. He said he had had a similar tumor, though perhaps rather smaller, in the axilla of the op-

posite side, and described so accurately the nature of the tumor as to leave no doubt of the truth of what he said. He died in consequence of the aneurismal tumor which I have mentioned, and which gave me an opportunity of examining, after death, the artery of the opposite side, in which the patient said there had been a pulsating tumor, which had gradually grown to the ribs, and been finally cured. I found the artery reduced to a solid impervious cord, which probably was the situation of the aneurismal tumor. There was a tumor about the size of my thumb—it was an aneurism that had undergone the natural cure, and was about an inch and a half in length.

There was a man in this hospital some time ago, who had aneurism of the femoral artery, that underwent a spontaneous cure. The patient is well, and is now going about. I will mention the case in connexion with another point in the history of aneurism. I have mentioned, that when an aneurism is cured by the natural process, the arterial tube on which the tumor is situated is obliterated; but perhaps I am not authorized in making the observation quite absolute. It is probable, in the case of an aneurismal tumor situated upon the aorta, where the arterial tube is very large, and where the perforation of the coats may be very small, so that the aneurismal tumor may be small in proportion to the size of the tube, that the aneurism may become obstructed and admit of spontaneous cure, without the tube of the artery being interrupted.

[Mr. Lawrence here exhibited a specimen of aneurism of the aorta, in illustration of this. The aneurism had been cut in two; it was a small tumor, about the size of a large walnut, and had become filled by a laminated coagulum. The aneurismal sac was firmly attached to the artery, and the coagulum had a firm smooth appearance. Mr. Lawrence also presented another preparation, where he said the same process seemed to have been going on; though here a considerable part of the cavity of the aneurism remained;—but a large quantity of laminated coagulum had been deposited, so that it was in the early stage—the process of obliteration not having gone quite so far.]

The symptoms of aneurisms are different, according as the affection is seated in an external or an internal artery. By *internal* aneurisms I mean those of the aorta and of the *arteria innominata*, which are developed either in the cavity of the chest or the abdomen, and which may proceed to a large size without shewing themselves at all externally. By *external* aneurisms I mean those that are formed on the principal arterial trunks of the upper or lower extremities, and of the neck. An external aneurism consists of a firm pulsating tumor, situated in the course of one of the arteries that I have

just mentioned, and is inseparable from such arterial trunk. I say that an aneurism is a *firm* pulsating tumor. In the early stage of the disease the tumor admits in some degree of diminution by compression; it is filled up with fluid blood, that has not begun to coagulate, and therefore you find that it yields to the pressure of the fingers, so that you can thus diminish the size of the tumor. Pressure on the trunk of the artery, between the aneurismal tumor and the heart, puts a stop to the pulsation, and renders the tumor in the early state somewhat softer and flaccid: pressure on the trunk of the artery, below the aneurism, renders the tumor rather more tense; but in proportion as the aneurism becomes larger, and as the laminated coagulum is deposited on its sides, the tumor loses altogether that soft compressible character, and becomes firm and unyielding. The disease of the arterial trunk interrupts or interferes with the regular current of the blood through the artery, and the consequent regular arrival of the blood in the various vessels seated beyond it. Thus you very commonly find that the pulse is either suspended or considerably weakened in those vessels which are seated beyond the aneurismal tumor. In case of an aneurism of the femoral or of the popliteal arteries, you will probably not feel the pulsation of the posterior or anterior tibial arteries, while the pulsation of those of the opposite side can be felt very plainly. The aneurism being on a large arterial trunk, which is usually accompanied by some of the nerves, the development of the tumor often interferes with these nerves, and produces considerable pain, either in the seat of the swelling, or frequently shooting along the limb in all directions; and this pain in some instances is extremely severe. The pressure of the tumor upon the trunk of the absorbent vessels, and upon the veins, occasions general swelling of the limb below the part, of an oedematous character. These circumstances lead, therefore, to a considerable impediment in the functions of the affected part, and the patient cannot perform the ordinary motions of the limb, or at least not perform them without great pain. Such are the leading circumstances which characterize an aneurismal swelling, when seated in one of the external arteries of the body.

Now the existence of pulsation does not of itself essentially characterize an aneurism; so that you cannot conclude from that circumstance alone that it is an aneurism. A solid tumor situated over a large artery will receive a pulsation from it. You know that if you place one knee over the other as you sit, the impulse of the blood through the popliteal artery will make the limb which is uppermost shake—you cannot possibly keep it still. You may suppose, therefore, that if a swelling were seated upon the popliteal

artery, the impetus of the blood through the arterial trunk would communicate the pulsation to it. In the same way in a swelling of the neck, you may have a pulsation communicated to it by the carotid artery. I have seen a swelling which has pulsed, and which was attended with an interruption of the pulsation in the arteries beyond the tumor, which, nevertheless, was not an aneurism. I had occasion, in a former lecture, to mention a case of fungus hæmatodes, where the tumor was developed in the head of the tibia. Now this tumor happened to be developed where the popliteal artery divides into the anterior and posterior tibial, and situated between the trunk of the vessel and the strong fascia of the leg which binds down the muscles at the upper part of the tibia and fibula. The tumor being thus situated, pressed on the trunk of the popliteal artery at its division, and the effect of the pressure was such as to prevent all feeling of pulsation in the anterior and posterior tibial arteries in the limb of that side; at the same time the tumor received from the artery as distinct a pulsation as is ordinarily found in aneurism. These circumstances in that case led to the opinion that it was an aneurism; however, after a little time had elapsed, the tumor made its way through the fascia of the leg, so as to extend externally. The consequence was, that the trunks of the posterior and anterior tibial arteries were relieved from pressure, and the pulse returned in them; at the same time the tumor, not pressing so strongly upon the artery, it lost the pulsation that had previously characterized it. When a tumor pulsates in consequence of being seated upon an arterial trunk, the pulsation consists in a rising and sinking of the general mass of the tumor—the whole tumor rises and sinks with the pulsation; but in aneurism, if you grasp the swelling, you feel that the tumor is distended; you have a sensation communicated to the hand as if fluid were injected into the swelling; the swelling seems to increase in circumference at each pulsation of the heart. The feeling is, therefore, very different from that communicated by a solid tumor placed over the arterial trunk. Again, another circumstance is to be taken into the account in the diagnosis of aneurisms and other tumors, namely, that even aneurismal tumors do not in all cases pulsate. Various changes may take place in the state of the aneurismal sac, which will be attended with a diminution or cessation of the pulsation; or the pulsation may be suspended for a time and return again.

Some years ago a gentleman came to town from the country, and placed himself under my care, in consequence of a swelling, supposed to be aneurism, in the middle of his thigh. He was sent to town by an intelli-

gent practitioner in the country; and when I came to put my hand upon the tumor, I was surprised to find that it did not pulsate at all. The limb was swelled, and the general circumstances in other respects corresponded accurately with the notion of an aneurism. I interrogated the patient closely as to the character of the tumor in its previous state, and he described to me so clearly that it had pulsed up to a certain time, and mentioned when the pulsation began to diminish, that I could not doubt that it was an aneurism; and inasmuch as the pain, the swelling of the limb, and all the general effects produced by an aneurismal tumor were undiminished, and, in fact, were rather increasing, I did not hesitate to apply a ligature on the femoral artery, in the usual situation, which was attended by a regular diminution of the size of the tumor; and there could be no doubt that it was a case of aneurism.

I had two patients under my care in the hospital with aneurism situated at the bend of the thigh, in which, at all events, during a considerable period of the existence of the tumor, no pulsation was sensible. The first was a young man, admitted under the care of my colleague (Dr. Latham), for what was considered rheumatic pain, affecting the lower extremity of one side. He had been some time under the care of Dr. Latham, when it was discovered that there was a considerable and firm swelling in the bend of the thigh. I saw him in consequence of this, and found a large hard swelling, without any pulsation, seated on the bend of the thigh, which I thought could only be regarded as a considerable swelling of the glands of the part. There was some degree of swelling, and considerable pain, in the lower extremity generally, and in consequence of this, the case was transferred to my care. The case was again examined very carefully, but no suspicion was entertained of its being an aneurismal tumor; and means were adopted on the suspicion of its being a chronic enlargement of the absorbent glands of the groin. I recollect receiving the case, when there were different medical persons present, among whom were some foreigners, who happened to be here at the time, and who examined the case with me; but none of them entertained any suspicion of the disease being aneurism. After the patient had been some time under my care, an attack of pain came on in the swelling, which led me to examine it again very carefully. I was examining it in various directions, to see if there was any evidence of matter being likely to form, or if it had any fluctuation: in examining this point, I became sensible that pulsation existed in the tumor—and, in fact, at the time I am now speaking of, there was a decided pulsa-

tion in the swelling. This increased considerably in the course of a few days, and at length the swelling pulsated as strongly and manifestly as any aneurismal swelling that I ever saw. The truth was, an attack of inflammation had come on in the sac of the aneurism, under which the pulsation, which before had ceased, was renewed. It was deemed proper to tie the artery in that case, but in consequence of the inflammation having already gone to a considerable extent in the sac of the aneurism, the patient died, although the operation, so far as the securing of the artery went, was successful. This gave me an opportunity of examining the case after death: it was found in that case that the femoral artery was obliterated in the way I have mentioned to you, by the pressure of the tumor, so that the probability is, that the aneurism might have gone on to a natural cure but for the inflammation that had occurred in the sac.

The other case of swelling, in the same situation, is the one that I have already alluded to as an instance in which a spontaneous cure of the aneurism took place; and as that case, in certain respects, is interesting, I will read you a few minutes I have made of it.—This was a patient 30 years of age, whose recent occupation before he came to the hospital was that of a porter. About Christmas 1823, he observed a lump in the bend of the right thigh, which he could not ascribe to any strain, blow, or other injury. It gradually increased, without pain; but in a few weeks it caused a general swelling and stiffness of the limb, which had confined him to his bed for seven weeks previously to April, when he was received into the hospital. At this time the bend of the knee was occupied by a large swelling, without a definite boundary, extending three inches below the crural arch: it extended upwards to within two inches of the navel, and it was felt through the abdominal parietes as a large firm tumor, about the size of the fist. The swelling was œdematous, with the thigh half bent; and at this time he suffered much from pain and want of rest. There was no pulsation in the tumor, and there had been none in its progress; at least the patient had felt none, and the surgeon who first saw him prescribed simple treatment, and assured him he would soon get well. This made up the patient's account; but as I was quite uncertain as to the nature of the swelling, I examined every circumstance of the case with great care, and particularly investigated the tumor, both with the naked ear and the stethoscope. At the time the former case occurred, auscultation had not come into fashion, and therefore no attempt was made to examine the tumor in that way. But in the instance that I have now mentioned, it occurred to me that possibly pulsation might be distinguished by the ear, though

it could not be felt; and, in fact, when I put my ear down to the swelling, I heard the pulsation as distinctly as you hear the pulsation of the heart by placing your ear on the side of the chest; though even at that time no pulsation could be felt with the hand. With the stethoscope the pulsation was equally distinct, but not more so than with the ear. There could now be no doubt about the nature of the disease, as after a time partial pulsation could be felt, and even seen. It is a curious circumstance, that in a tumor where, up to a certain time, no pulsation existed, that such changes should occur as again to induce pulsation. In the instance that I am now mentioning to you, the pulsation of the aneurismal tumor became as strongly marked as that of any other aneurism I ever saw. At this time the swelling had increased so as nearly to reach the navel, the entire limb being enormously swollen. The operation was considered inadmissible: tying the aorta was suggested by an eminent surgeon who saw the case, but I considered that the chance of a natural cure, however slight, was preferable. The pulsation in the tumor gradually became feeble, and at last it seemed that the aneurism grew less, and the limb began to extend; the pain ceased, and the general health improved. The patient felt so well by the end of September, that he left the hospital at his own desire. * * *

His recovery since he left the hospital has been progressive. The thigh is still swollen, but the tumor is less; and though the limb has become stiff, he can walk about with crutches; he is in good health, and looks well. The first part of these minutes I made in October 1823. The patient was at the hospital not long ago—in November 1829, when I made the concluding part of the memorandum. It thus appears probable that the aneurism was filled up by laminated coagula that the pulsation was thus suspended, and that subsequently the coagulum has been absorbed; so that what remains is some thickening and induration, the consequence of the deposition arising from the inflammation of the part, and the general tumefaction of the limb.

With respect to the symptoms of *internal* aneurisms, so long as they continue within those cavities of the body in which they are first developed, there are no circumstances which characterize their existence sufficiently decisive to enable you to know that aneurism exists. An aneurism seated about the arch of the aorta, may interfere with the important organs which are in that situation. The development of a tumor in that part cannot fail, by pressure on the various parts there, to produce serious effects, such as affections of the breathing, cough, pain, and so forth. A tumor in that situation very soon comes to press upon the trachea and œsophagus, and then may produce various symp-

toms; but until the tumor makes its way externally, so as to shew itself at some point of the external surface of the chest, and be recognized as a pulsating tumor, you cannot be certain that these depend on aneurism. The symptoms, in fact, frequently are of a nature not calculated to give the least clue to the existence of that disease.

I remember the case of a patient brought to this hospital, who had been subject for a short time only, according to her own account, to serious attacks of difficulty of breathing. She described these as so serious, that in three or four that had recently occurred, she had been so much affected that she thought she should have died in the fit: she could not fetch her breath, and in fact her description made one suppose, that there must be some very serious disorder seated about the pharynx or the trachea, interfering with the functions of those parts. We speculated on the probable nature of her disease, and considered what measures it would be proper to adopt in case, of a paroxysm coming on, and we were considering whether it would be advisable to make an opening in the trachea, and the opinion seemed to be rather in favour of that measure in case an attack of difficulty of breathing should take place. The woman had an attack of this kind in the night when no surgeon was at hand, and unfortunately she went off in this attack. This afforded me an opportunity of examining her after death, and I found an aneurism of the *arteria innominata* seated behind the sternum, about the size of half an orange, that pressed upon the trachea, and it slightly indented the anterior part of the tube, so as to make a slight inequality upon its surface; but I should not have supposed that it was sufficient to obstruct the tube so as to prevent the breathing, and in fact that it did not essentially do so was clear from its ceasing in the intervals of the attacks. But spasmodic attacks, at least such as for want of a better name we must call spasmodic, came on, attended with difficulty of breathing, and indeed that difficulty went the length of suffocation. You will recollect that there is but a small space about the upper part of the chest; the arch of the aorta, the *œsophagus*, and a variety of important vessels and nerves, are confined together in this space; and it is the situation in which aneurismal tumors of the arch of the aorta, or those of the *arteria innominata*, are developed. These tumors, therefore, cannot proceed to any great extent without interfering with the functions of the parts. Thus you find frequently that aneurisms in the arch of the aorta have terminated existence by bursting in the trachea or *œsophagus*. It has been known that tumors seated here have broke into the pulmonary artery, and such tumors have occasionally been developed without producing marked symptoms suffi-

cient to enable you to determine that the case was one of aneurism.

Aneurism is sometimes produced by obvious and direct external causes. A wound of an artery may produce an aneurism. I have already mentioned to you how the wound of an artery may be attended with effusion of blood into the surrounding cellular texture, and how blood escaping from an arterial tube in this way may be injected into the cellular texture of a limb extensively, or even generally, and I mentioned to you that such a case has been called *diffused false aneurism*; but, in fact, it should not be called aneurism at all; it is merely a case of a wounded artery, with ecchymosis or effusion of blood into the cellular texture, and has not any thing of the character that properly belongs to aneurism. However, the wound of an artery sometimes produces a circumscribed pulsating swelling. The arterial wound may be closed by coagulum, or in some other way, at the time of the accident, and this slight closure of the wound may give way, and be distended into a regular aneurismal swelling. It is in this manner that aneurism of the brachial artery takes place in consequence of a wound from venesection; and that aneurism of the temporal artery sometimes follows the wound of arteriotomy. I have seen it follow the bite of a leech;—one would suppose that it must have been a very strong leech to produce this effect. This is called a *circumscribed false aneurism*, and in all respects the nature of the affection and its treatment correspond to that which we shall have to state about aneurisms generally.

Then aneurisms sometimes appear to be produced by external violence of a different kind. The patient who has an aneurism says he has received a blow, or met with a strain, or that he has slipped, and, endeavouring to save himself, has felt something break, or crack, or give way; in these modes patients frequently account for the occurrence of aneurismal tumors.

Certain other external circumstances seem to have some influence in the production of aneurism, though we cannot point out exactly, perhaps, how they do so. It has been observed that popliteal aneurisms take place more frequently in those who keep their knees habitually bent, such as in postillions, taylor, and some others.

With respect to most external aneurisms, and even a greater proportion of the internal aneurisms, we must observe that the causes which lead to them are very obscure. Indeed, I do not know that we can assign any very satisfactory cause for their occurrence. We sometimes see instances in which aneurisms of the aorta arise and run their whole course, destroying the patient, without the surgeon being aware of their existence: I have known an instance in which a gentle-

man coming home after being out for a ride, and going to take off his boots, has fallen down dead from the bursting of an aneurism of the aorta, though he was not aware of labouring under any disease whatever. There are circumstances, however, whatever they may be, that act extensively on the arterial system; for we not uncommonly find aneurisms existing in more than one artery in the same individual. I have mentioned an instance of one case where aneurism took place successively in each axillary artery, and in nearly the last case I operated on in aneurism of the femoral artery, there was a small aneurismal tumor of the femoral artery of the opposite side. Several instances have been known in which patients have had external aneurisms and aneurism of the aorta simultaneously. They have died of the disease of the aorta, after having had external aneurisms operated on.

Aneurism occurs more frequently in the larger than in the smaller arteries of the body: it is most frequent in the aorta and innominate; next in the external iliac, femoral, brachial, and carotids; while in the arteries of the third and fourth order, such as the radial and the ulnar, the anterior and posterior tibial, and the interosseal, it is extremely rare—hardly ever seen there, except in consequence of a wound, or some external cause. It is much more frequent in arteries of the lower than in those of the upper extremities; indeed, it has been stated by some, that hardly an instance can be produced of any aneurism below the axilla which cannot be referred to a wound, or some obvious external cause. It is also found that aneurisms, as well as other diseased changes of the arterial coats, are much more frequent in the male than in the female subject. Mr. Hodgson, in his valuable work on Diseases of the Arteries and Veins, has given in a table a list of all the cases of aneurism that he had seen, which will shew you the comparative frequency of them. Mr. Hodgson's table includes 63 cases altogether; of these 21 were aneurisms of the arch of the aorta and arteria innominata, 16 occurring in males and 5 in females;—8 were cases of aneurism of the descending aorta, 7 males and 1 female;—2 cases of carotid aneurism, both in the male;—5 cases of aneurism of the subclavian, all in the male;—12 cases of inguinal aneurism, all in the male;—15 cases in the femoral and popliteal, of which there were 14 in the male and 1 in the female. So that in a total of 63 cases of aneurism, 56 were in the male and 7 in the female subject. This table also shews you the other circumstances that I have mentioned, the great frequency of aneurisms in the larger arteries; for out of 63 cases, 29 were of the arch of the aorta and the arteria innominata; and it exhibits the greater frequency of aneurisms in the lower than in

the upper extremities—there are 27 cases of aneurism of the lower, and 5 only of the upper extremity.

There are some rare instances of aneurism being found in some of the smaller arteries. I think there is a preparation in the museum of an aneurism of the splenic artery; there is here one of the renal artery; and in some instances aneurism occurs in the arteries of the head—as the basilar, and in the external branch of the carotid, and the branch that joins the carotid and the vertebral arteries: these, however, are rare occurrences; I believe there is no such thing known as aneurism of the pulmonary artery, at least I never read or knew of such an instance.

Then having seen the mode in which aneurisms are sometimes spontaneously cured, we naturally inquire whether we possess any means which are capable of placing the aneurismal tumor in such circumstances as would bring about this spontaneous cure, or as would favour its occurrence? The surgical operation of passing a ligature on the artery, between the aneurismal tumor and the heart, is an effectual mode of producing changes by which the aneurism may be got rid of; but in an aneurism of the aorta we cannot have recourse to this operation. It is true that the aorta has, I believe, in two instances at all events, been tied; but I believe the result of those operations were not such as are calculated to lead to a repetition of them. Aneurisms of the aorta, therefore, may be considered as out of the reach of the surgeon. Aneurisms, however, of the main trunks of the upper and lower extremities, and those of the neck when seated near the trunk of the body, may all be considered the subjects of surgical operation.

In some instances patients do not choose to submit to an operation; it has therefore been considered desirable to find out some course of proceeding, not involving an operation, that should be capable of bringing about this natural cure of aneurism. Direct depletion by loss of blood, abstinence, and rest, are the great means of reducing the force of the circulation generally, and thus they contribute towards the reduction of the force of circulation in the tumor, which circumstance we might suppose likely to lead to the deposition of a coagulum in the sac of the aneurism, so that it might become obstructed, and a natural cure thus be accomplished. This course of proceeding has been extensively tried, particularly in aneurisms of the aorta; and there is the further reason for the adoption of this course of proceeding, that aneurisms of the aorta are often attended with very considerable local suffering, considerable inflammation of important organs, which are more or less interfered with by the development of the tumor; considerable excitement of the system, with symptoms of a feverish character—symptoms which, whether the aneurism is to

be cured or not, are all likely to be benefitted by the plan of depletion. This plan has been tried extensively abroad; it was adopted by an Italian surgeon of the name of Valsalva; and Morgagni, who was an apprentice of Valsalva, has mentioned that he (Valsalva) had employed this method in many cases with very great success. He seems to have employed it very effectually—that is, he reduced his patients so much, that they could hardly lift their hands from the bed. The treatment he advises consists in venesection, purging, a very reduced diet, and absolute rest in the horizontal posture—that is, in a combination of all those circumstances which are calculated to reduce the force of the circulation, to diminish the impetus of the blood in the tumor, by which obstruction of the aneurism may be affected, and the circulation brought into that quiet, or rather languid state, in which you may suppose that the separation of the fibrin of the blood, and a deposition of laminated coagulum, would be promoted.

I have several times adopted this treatment in cases of aneurism of the aorta, and often with very considerable benefit; first, in relieving those symptoms of excitement that I have already alluded to, and secondly, in checking the progress of the aneurismal tumor, retarding its increase, and making it stationary. In the course of the last year a patient who was in the hospital for aneurism of the descending aorta, accompanied with a manifest protrusion externally of the aneurism in one part, was treated in this way, and the external protrusion gradually diminished, and ultimately entirely disappeared. I must observe, however, that I have not seen any case entirely cured by this treatment. It is a mode so repugnant to the inclinations and to the prejudices of the patient, that we find they will not readily submit to it. At first, till they have derived relief from the urgent symptoms, they are well enough disposed to yield obedience to your directions; but in order to have a chance of curing the aneurism, we must pursue the treatment for a considerable time. When, however, there is no longer any apprehension on account of the symptoms, and patients feel themselves very feeble, they begin to think that something is required to strengthen them; they wish you to let them have some meat and some beer, not to be bled again, and so forth. Now, whenever I hear hints of this kind, I know that it will not do to follow up the plan; for if you do, the patients will decamp. We generally find that patients and their friends, and even the nurses, are all in a conspiracy against us; they do not understand the principles of Valsalva. Thus I have not succeeded in these cases in following up even one to a satisfactory termination, though I have seen so much good done in a variety of

instances, as to lead me to suppose that if the plan were persevered in, it might be productive of a complete cure; at all events, I have seen that the progress of aneurism may be considerably checked by this plan of treatment.

With respect to bleeding in these cases, it is necessary to proceed with a little caution; for we find by experience, in serious affections of the heart and large vessels, syncope sometimes comes on, which will terminate fatally, and that not uncommonly persons under such affections will die suddenly: now we must not run the risk of bringing on that event by venesection. You should therefore be careful not to take a large quantity of blood in cases of this kind at once, but rather repeat the loss of blood occasionally. It may be a question whether any assistance can be derived where the tumor appears externally, by applying cold lotions, or even ice, to it—whether such applications have any tendency to promote coagulation in the tumor? But we find when cold applications are used, such as ice, the application is so painful to the patient that it cannot be well persisted in.

I should mention as an auxiliary, the employment of digitalis. This is a case in which, if we could produce the effect that digitalis sometimes has, viz. the reduction of the force of the pulse, the object which we have in view would be materially assisted.

LECTURE XLIV.

History and Treatment of Aneurism, continued—Pressure—Application of Ligatures—Secondary Hæmorrhage—Ligature beyond the Tumor—Varicose Aneurism.

I SPOKE to you, gentlemen, in my last lecture, of the method of treating aneurisms, particularly those of the aorta, by venesection, abstinence, and rest; with other means calculated to lower the force of the circulation, which is called the method of Valsalva; and I stated to you that in no case had I witnessed any example of perfect cure effected by that mode of proceeding. I believe that others may have been more successful in this respect than I have been. At all events you find, in Mr. Hodgson's work on the Diseases of Arteries and Veins, several cases in which there seems reason to suppose that aneurisms of the aorta were completely and permanently cured by this plan of treatment. I have pleasure in directing your attention to this work of Mr. Hodgson's, as containing a very complete, and at the same time a very clear exposition of what we know relating to the important subject of diseases of the arteries and veins. You will find in it a very full and satisfactory account of the physiological and pathological principles applicable to this subject, with a very valuable col-

lection of facts illustrating them ; while the whole is arranged in a very clear and perspicuous manner.

The method of Valsalva is not strictly confined to aneurisms of the aorta. There may be external aneurisms in which there is a good deal of local excitement, and disturbance of the system connected with it, in which the patients will not submit to operation, where you may have recourse to that plan of treatment as the next best measure.

I mentioned to you also in my last lecture, that an aneurismal tumor sometimes does not present the most striking character of the disease—pulsation ; that is, that you cannot feel pulsation in the tumor. And I also mentioned to you that there are some instances in which pulsation cannot be felt, but in which it can be heard, either by the ear directly applied to the aneurismal tumor, or through the medium of the instrument called the stethoscope. The sound that is communicated in either of these cases is very peculiar ;—it is produced by the passage of the stream of blood from the tube of the artery into the aneurismal tumor. The blood passes through a comparatively contracted orifice to enter a large cavity ; and each jet of the blood propelled by the contraction of the left ventricle into the aneurismal tumor, produces a sound which is something like that of the stroke of a pair of bellows in blowing them. [Mr. Lawrence here imitated the sound.] You hear a succession of these ; and hence the French have characterized this noise by the apposite term *bruit de soufflet*: *soufflet* is the French for bellows, and the expression means a noise like that of a bellows :—we cannot have a comparison more clearly illustrating this.

Pressure has frequently been tried as a mode of treating aneurisms, and two methods of applying it have been adopted ; one in which the aneurismal tumor and the artery above it have been subjected to pressure, and another in which pressure has been applied simply to the arterial tube. In the former mode of employing pressure compresses have been placed upon the aneurism, and also upon the trunk of the artery above it ; that is, on the trunk of the artery between the tumor and the heart. These compresses have been bound firmly upon the limb, so as to create a general pressure on the aneurismal swelling, and that part of the arterial trunk immediately contiguous to it ; and those who have adopted this have combined with it the other treatment, that I have already described to you under the name of Valsalva's method,—that of depletion, rest, and so forth.

Now we cannot easily perceive how pressure on the external portion of an aneurismal tumor can be likely to prevent the growth of the swelling, or diminish its size ; and I

think we may conclude very safely, that the binding of compresses upon the artery above the tumor will not prevent the passage of blood from the artery into the sac. Considering the matter *à priori*, I think we should not expect any very efficacious influence from this mode : and such is the result of experience ; for in the great majority of instances in which pressure is applied, it seems as unavailing as we might expect.

It has been proposed, however, to subject the artery immediately above the aneurismal tumor to effective pressure, so as actually to place the sides in contact, and keep them so, in expectation of lymph being effused so as to produce adhesion, and consequently obliteration of the tube. Now this can be effectively done in the horse ; that is, if we apply a tourniquet where the artery runs along the leg—screw it tightly, and leave it on for three or four days, inflammation will be excited in the coats of the artery, and the artery will become obliterated in this way. But this cannot be borne by the human subject : the pain is so excessive from pressure of that nature, that it cannot be tolerated even for a short time. You might easily anticipate this result when you consider what kind of pressure is necessary in amputation, in order to prevent the flow of blood through the limb. You find it necessary to screw the tourniquet tightly to prevent the blood from flowing through the artery ; and you find that the pressure thus produced is so painful, if prolonged beyond a few minutes, that the patient is not able to bear it ; and you can easily suppose that no individual could bear the prolonged pressure that I have alluded to, if extended to three or four days.

Without asserting, then, that pressure has in no instance either cured, or contributed to the cure of aneurism, we may say, at all events, that in a vast majority of cases it has totally failed. We may state safely, that a person cannot bear the application of pressure in a degree adequate to produce closure of the artery, and consequently that this method does not deserve any confidence as a general means of treating aneurism ; so that we are not surprised that it has passed into disuse. The only effectual mode, then, of proceeding, is the surgical operation of tying the artery above the aneurism, or at the place where it opens into the swelling. This is, at all events, a rational mode of proceeding ; and, when the operation is performed in a proper way, it is both safe and effectual.

The old operation for aneurism, and indeed that which was performed up to a comparatively recent period, was a very formidable proceeding. It consisted in laying open the aneurismal tumor in its whole extent, clearing out the coagulum it contained, and securing the orifice of the artery, where

it entered the sac, by a ligature including either the upper or lower, or both of the orifices. Now, when you consider that it is by no means always a very easy undertaking to lay bare the artery, to find, and tie it, even when you choose your own situation for seeking it, you will understand that great difficulty must have been experienced in tying the artery where it was attempted in the way I have described, when the orifice of the vessel was connected and implicated with the surrounding parts, and probably deeply seated; as for instance in the ham, where the artery lies close upon the bone, and where you might have perhaps five or six inches in depth of the aneurismal sac to go through before you arrived at the orifice of the vessel. You must consider that the attempt to secure the artery in such cases used to be made when the principles applicable to the ligature of arteries were totally unknown, and consequently the most rude and unscientific proceedings were adopted. Then you must consider farther, the effect that must have been produced by the inflammation that would arise in a large aneurismal sac thus laid open,—leading to suppuration and occasional mortification. When you take these circumstances into view, you will not be much surprised that these old operations for aneurism were almost invariably fatal, and that it was an uncommon circumstance for a patient that underwent this operation to escape with his life. Hence surgeons had very much abandoned it, and considered it better for patients in whom it could be performed, to submit to amputation rather than to such an operation. Mr. Pott mentions aneurism of the popliteal artery as a proper case for amputation, he considered the old operation so desperate an undertaking.

We are indebted to Mr. Hunter for the principle of the modern operation for aneurism. It has been found, however, that some of those who preceded him, particularly some of the older writers, have given a description more or less clear of an operation something similar to that which he proposed for aneurism, so that it is doubtful whether we ought to ascribe to him entirely the merit of originality. There can be no doubt, however, that the discovery is thus far due to him, that he had no acquaintance with those passages in the old writers in which the operation has been described, or supposed to be described; and that he arrived at the conclusions that led him to propose this mode of operation, from a physiological examination of the principles applicable to the treatment of the disease. In this mode the artery is tied at some distance from the aneurismal sac; that is, the ligature is placed upon it in a situation in which it is tolerably accessible—where it can be easily exposed and taken up, and the aneurismal sac itself is not touched—it is left entire.

The consequence of this mode of proceeding is, that the arterial trunk becomes obliterated where the ligature has been applied to it, so that the direct impulse of the heart is removed from the aneurismal sac. The pulsation of this ceases; and the tumor itself generally diminishes, in some degree, immediately after the artery is tied. However, in consequence of this removal of the propelling force by which the aneurismal sac is kept in its distended state, the blood no longer circulates freely through it, but coagulates; and, in fact, the sac becomes completely filled with coagulum, so that the further circulation of blood through it is completely cut off. When this is effected, the aneurismal sac becomes contracted—the coagulum which it contains is then removed by absorption; and, in fact, the aneurism undergoes the same kind of spontaneous obliteration which I mentioned to you as taking place occasionally independently of any operation. In order to produce the changes that I have mentioned it is not necessary that the circulation through the sac should be at once and immediately suspended; for, in fact, the ligature of the arterial trunk above the tumor does not produce this effect. The freedom of the arterial communications is so great, that although the trunk of the femoral artery be tied on the front of the thigh, blood passes into the aneurismal sac below from vessels arising above the ligature, although not with a sufficient degree of force to produce pulsation in the tumor. But the disposition in the parietes of the aneurismal sac to contract, and in the blood to coagulate, are stronger than the distending force, which now produces but an enfeebled current, and the consequence is that the blood coagulates. That the application of a ligature is not always sufficient at once to render the blood stationary in the aneurismal sac, is clearly proved by this circumstance, that in some cases the pulsation returns in the aneurismal sac. When the ligature has been tied it is immediately arrested; but in the course of a few hours, in some instances, the aneurismal sac begins to beat again, and the surgeon is apt to be apprehensive that the artery is not tied, or that something has occurred to render the operation abortive. This is observed in cases both of popliteal and carotid aneurism: however, the pulsation thus produced is but a feeble one;—it lasts for some time, then gradually becomes diminished, and ultimately disappears entirely.

The mode of cure, so far as the aneurismal sac itself is concerned, under the operation as it is at present practised, is just the same as one of the spontaneous cures that I have already had occasion to describe to you, and which takes place by the gradual obstruction of the sac by coagulum. Now, before you are fully acquainted with all the resources of the animal economy, particularly

as regards the circulating system, you might entertain an apprehension that when the main artery of the limb was obstructed by a ligature, the limb would be inadequately nourished—that the blood would not obtain access to the parts beyond the obstruction, and that there would not be a sufficient quantity to carry on the purposes of the animal economy. We find, however, that the communications of the smaller arteries are so free all over the body, that when an arterial trunk is tied in any situation where it is accessible to surgical operation, the parts beyond the situation of such ligature are always adequately supplied, so that no doubt need be entertained on that point in any case. If you place a ligature on the trunk of the aorta, just above the diaphragm, in the dead subject, and if you then insert an injecting tube into the mouth of the aorta, where it comes from the left ventricle of the heart, and throw water into the vessel, you find that it gains access to the parts below the ligature; that, for example, if you open one of the tibial arteries, the water you inject into the orifice of the aorta will keep up a continued stream, even although you have placed a ligature on the descending aorta—so that there is a sufficient freedom of circulation to carry on a supply of blood, even if the aorta itself were tied. You may suppose, that although this takes place in the *dead* subject, it might not equally occur in the *living* subject; but the aorta has been tied in the dog frequently—and it is not difficult to tie the aorta, where it lies on the lumbar vertebrae in the dog; you can tie the aorta and the animal will recover, the parts below the situation of the ligature being perfectly supplied with blood. I have already mentioned, that in two instances the aorta has been tied in the human subject. In both these cases it was tied between the aneurismal tumor and the heart, and there did not appear to be any deficiency in the conveyance of the blood to the lower extremities. The patients, however, did not live long enough to shew the mode in which the circulation was carried on; but the twelve or eighteen hours that they survived were sufficient to prove the fact, that the parts beneath were supplied with blood. The *arteria innominata* has been tied twice in the human subject, and in both cases the circulation was carried on in the upper extremity, and in the right side of the head—in one instance for three weeks, and in the other for five or six weeks—for so long the patients lived. The trunk of the left subclavian has been interrupted by aneurism, yet the left upper extremity has been adequately supplied. The axillary artery, and the femoral artery, below the crural arch, have both been tied in consequence of wounds, where there has been no previous disease existing, and yet the extremities in such instances have been ade-

quately nourished. You may consider, therefore, that what is called the collateral circulation—that is, those modes by which the circulation is carried on when the main arterial trunk is tied, is adequate to the supply of the parts situated beyond the ligature, whenever you can apply such ligature in the treatment of aneurism.

In the first instance, however, perhaps the circulation is not so vigorous in the limb of which the main arterial trunk is tied, as it is in the natural state. Sometimes, indeed, partial mortification has taken place, as of a toe, where the femoral artery has been tied: this, however, occurs very rarely; and I believe there are but two or three instances where more considerable mortification has occurred in the upper or lower extremities, in consequence of tying arterial trunks. But though this is uncommon, still, in consequence of the possibility of such an occurrence, I should deem it right to adopt all proper means for preserving the heat of the limb, until the circulation be fully established. We should take care not to let the limb be exposed to cold, but to preserve it as nearly as we can at the natural heat.

You will probably inquire, what is the time at which the operation for aneurism should be performed? Whether we should do it as soon as the existence of the aneurism is known, or whether we should wait for some time longer, till the aneurismal tumor has acquired a certain bulk? A notion has very commonly prevailed, that it is desirable to defer the operation for aneurism, under the idea that the obstruction of the arterial trunk increases the collateral channels, and that they gradually become enlarged, so as to be more adequate for carrying on the circulation. It has been advised, therefore, to postpone the operation, not on account of any reason arising from the nature of the disease itself, but from that which I have just mentioned, namely, to give a greater security to the performance of the circulation through the collateral channels. Now it is not necessary to defer the operation on this account, for the resources of the animal economy are fully adequate for it, if we tie the artery as soon as we ascertain the existence of the disease; but the postponement of the operation, which is not necessary for the reasons that I have mentioned, in other points of view is actually prejudicial. The enlargement of the aneurismal tumor interferes in various ways with very important functions, and produces changes that subsequently are more or less injurious in the parts immediately surrounding. Muscles, tendons, and nerves, get involved in the aneurismal tumor, and become firmly connected with it: sometimes the nerves are pressed upon, so as to be spread out and flat. The progress of the tumor when it reaches a bone, causes its absorption. I have seen a

large aneurism in the ham allowed to go on to such a size, that considerable absorption had taken place in the posterior part of the condyles of the femur; and again, when an aneurism takes place in the axillary artery, below the clavicle, the tumor is seated between the pectoral muscle and the parietes of the chest, and will produce absorption of the ribs. If the tumor increases towards the cavity of the chest, it may be productive of serious consequences, without becoming very large. I have seen one or two ribs so far absorbed, as to give way at the back in examining the parts after death. Again, when the neighbouring tendons and muscles, and parts of that kind, are involved, even if we cure the patient by operation, considerable stiffness and imperfection of the motions of the limbs will be the result. For these various reasons, then, it is advisable to operate for aneurism at an early period of the affection; in fact, as soon as the existence of the disease can be clearly and distinctly recognised. There is no kind of reason for deferring the operation; on the contrary, the evils that I have just mentioned are aggravated by its postponement.

The mode of performing the operation is simple. The only object you have in view is to tie the trunk of the artery in such a way that the sides of the vessel may unite, and the tube become obliterated. All you have to do, therefore, is to cut down upon, and expose the vessel, with as little disturbance to it as possible;—to carry a ligature under the artery, detaching it to as small an extent as possible from its surrounding connexions—in fact, if you use a proper aneurismal needle, you can convey a proper ligature under the artery without detaching it further than simply in the track of the needle. Sometimes persons have an idea that they ought to take the artery between their finger and thumb, or put their finger under it, before they apply the ligature; but you will recollect, that in order to effect the union of the sides of the artery, you want a perfect state of the circulation in its coats. The coats of the artery derive their supply of blood from the parts immediately surrounding the tube, and if you detach them extensively, you cut off this supply. If, therefore, in applying the ligature, you extensively detach the surrounding parts, you cannot be surprised that the deposition of lymph does not take place, and consequently the obliteration of the artery failing to occur, that hæmorrhage should afterwards ensue. On the contrary, if you apply a ligature where the artery is closely connected to all the surrounding parts, it receives a regular supply in the ordinary way, and you have every security that this process will be carried on efficiently.

Then with respect to the kind of ligature, and mode of tying it—all the principles that

I have already mentioned in relation to the same subjects, in speaking of wounded arteries, are applicable here. You should employ a small, round, firm ligature, and tie it tightly. You cut the coats of the artery in the way that I have already described—lymph is poured out—it becomes organized, and the wound in the sides of the vessel is united by adhesion. Now when the operation was first introduced by Mr. Hunter, the proper mode of tying an artery was not understood, and hence a great number of cases of failure ensued—that is, in a great number of instances hæmorrhage took place at a greater or less distance of time after the artery was tied. The artery having been extensively detached, and perhaps tied with a large ligature, that bruised the coats, it ulcerated, and effusion of the lymph, necessary for sealing up the end of the artery, did not take place; and thus, when the ligature separated, secondary hæmorrhage came on. The occurrence of these untoward circumstances led surgeons to suppose that it might be advantageous to put a ligature higher up on the vessel, without drawing it tight—or to place a ligature under the artery, ready to be drawn when bleeding came on: these were called *ligatures of reserve*, and by the French *ligatures d'attente*. I think in one case Mr. Hunter employed four ligatures—tying two, and putting two on loosely. You can easily conceive what an excessive detachment of the coats of the artery there must have been, even in order to place four ligatures around it. When, too, you consider the effect which a seton produces in other parts of the body, you can suppose what an inflammation would be produced in the arterial tunics and neighbouring parts by four ligatures—in fact you would be pretty near the mark if you gave them another name, and called them four setons instead of ligatures.

Then an idea arose, that where hæmorrhage took place after an operation, it might be ascribed to some injury which the coats of the artery sustained in tying them; and thus it was proposed, in order to avoid pressing and injuring the parts, that cork, wood, and other substances should be laid upon the vessel; and that a broad ligature should then be applied, so as to press on these foreign substances, but without tying it very tightly. In a case operated on by Mr. Cline, a piece of cork was put on the artery, and tied with a tape; and a variety of other mechanical contrivances have been used to press upon the artery, in order to obviate this much dreaded circumstance—the occurrence of secondary hæmorrhage. There is no doubt that these contrivances were just the very means to favour, or rather insure, the occurrence of the accident; and so long as such principles prevailed, you cannot be surprised that surgeons were

frequently troubled by the occurrence of this secondary hæmorrhage, and that many patients were lost in consequence of it.

In proportion as the principles connected with the application of ligatures became more clearly understood, all these practices were abandoned, and surgeons are now contented with passing single small ligatures round the vessels, detaching the parts to as small an extent as possible, and tying them tightly. Thus secondary hæmorrhage is now rarely heard of in aneurism. I never saw secondary hæmorrhage occur after aneurism, where the operation had been performed properly. I have never seen it take place in any instance in which I have myself tied the artery in aneurism, and therefore I conclude, that in tying them as I have described, it is not much to be dreaded.

I should mention, that bleeding sometimes takes place after an operation for aneurism, when the ligature has separated from the artery, and the cause which produces it is not clearly understood; for several ounces, perhaps half a pint, or even a pint, of arterial blood will be suddenly lost from the wound; but the hæmorrhage being stopped by pressure, it frequently never recurs again.—You are not therefore to suppose, that because hæmorrhage of this kind takes place, it is necessary to proceed immediately to tie the artery higher up. In all such cases we should, in the first place, try the effect of pressure, and in the majority of instances you find that pressure, when thus employed, completely restrains the bleeding, and that this does not recur. A similar occurrence occasionally takes place after amputation, when the ligature separates from the main artery. If, however, the bleeding should be repeated, I know of no remedy except that of tying the artery higher up.

Secondary hæmorrhage may perhaps arise, in some instances, in consequence of the diseased state of the artery where the ligature is applied. We cannot, however, by any means say that the occurrence of aneurism presupposes disease in the artery of the limb where it takes place. That diseased condition in which there is an opaque change, or cartilaginous or osseous deposition forming on the internal coats of an artery, seems to be a kind of change that takes place in elderly persons, in consequence of age; and it is not in the habit of producing aneurism. In many instances of aneurism we find that the trunk of the femoral artery, (supposing, for example, the aneurism is seated in the ham), seems as healthy as any artery can be. Undoubtedly the artery may possibly be in a diseased condition in the part to which we apply the ligature—that is, the texture may be thickened, or there may be some of that opaque deposition on the internal coat; but, at the same time, the existence of such a state of the artery by no means necessarily

leads to the occurrence of hæmorrhage. I have many times seen arteries in that state in amputation, where no hæmorrhage has taken place on the separation of the ligature. If, however, hæmorrhage arose from the diseased condition of the coats of the artery, the case would be very unpromising, because the probability is that the same diseased state would exist in the artery higher up.

I have mentioned to you that the aneurismal swelling gradually lessens, and is ultimately removed by absorption, after the operation. In some instances, however, inflammation takes place in the aneurismal sac, and proceeds to suppuration, and the matter either escapes by the abscess bursting, or we evacuate it by an artificial opening; and I have seen this happen sometimes at a considerable distance of time, from the ligature being placed upon the artery. The occurrence of inflammation in the aneurismal sac is attended with a good deal of local uneasiness, and with very considerable constitutional disturbance. The aneurismal sac, in fact, becomes converted into an abscess; and when we open such abscess, we frequently find that there is a quantity of matter mixed with coagula of blood, and in that state we shall usually find that the contents of the sac are extremely fetid. When we thus come to give issue to a large quantity of stinking pus and coagula of blood, we see pretty clearly the reason why the patient has suffered the serious constitutional disturbance which is generally connected with this event. I have seen this take place in three or four instances, and in none of these has hæmorrhage taken place when the sac was opened. In all the cases where I have found it necessary to open the sac and evacuate the contents, even if the current in the artery had not been previously obstructed by the deposition of a coagulum, probably the changes that had taken place in the sac would have been sufficient to account for the absence of hæmorrhage. All the cases that I have seen have gone on perfectly well after the sac has been opened and the contents evacuated.

Another mode of operating has been proposed, in certain cases of aneurism in which the situation of the tumor has been such as not to admit of the proceeding that I have now described. When an aneurism of the femoral or of the axillary artery reaches so close to the trunk of the body that there is not space for the application of the ligature between the tumor and the heart, or when an aneurism of the carotid artery is situated in the same position as regards the upper part of the chest, it has been proposed to place a ligature on the artery beyond the aneurismal tumor. This principle originated with a French surgeon, of the name of Brasseur, who does not seem himself to have reduced it to practice. It was tried by another

French surgeon, named Deschamps, but the circumstances under which it was tried, and the mode in which it was done, prevent us from drawing any clear inference from the result of that case. It was reserved, in fact, for Mr. Wardrop to repeat this operation, and bring it to the test of practical experience, which he has done within the last few years; and he has published a work on the subject, in which he has explained the principle of the operation, and given some interesting details of his experience.

You are aware that the question whether tying the arterial trunk *beyond* the aneurismal tumor be capable of leading to its cure, is entirely one of experience, and can only be solved by an appeal to facts; and in order to determine it, we require, perhaps, a considerable number of facts more than we at present possess. The circumstances in which an aneurism is placed, in reference to this operation, are not always alike; in fact, we may distinguish two cases in which the results of this operation might be very different. In the first place, we might reasonably expect it to succeed if we could place a ligature upon the artery leading from the aneurismal tumor, under circumstances that should entirely prevent the current of blood through the aneurism from going on; we might expect that the same result would ensue as when we cut off the supply of blood by placing a ligature between the tumor and the heart. But there are very few arteries so circumstanced—perhaps the carotid is almost the only one. If an aneurism be situated on the lower part of the carotid artery, and if we have space to tie the common carotid beyond the aneurismal tumor, we know that no branch is given off between the ligature and the aneurism, and consequently that there can be no blood passing through the tumor; we might, therefore, expect that a coagulum would form, and lead to the cure of the aneurism. Mr. Wardrop first tried the operation in a case of that kind, and the success was complete. It appears that he again tried it in a case of carotid aneurism, and that the operation was complete in that case also, so far as the reduction of the aneurismal tumor went, but the patient unfortunately died of hæmorrhage from the upper end of the artery that was tied—from the remote end; a circumstance which, however, does not at all diminish the force of the inference that is to be drawn from the case, so far as it regards the principle of the operation. When, however, we come to aneurism on the trunk of the axillary, or of the femoral artery, the case is different. If we tie the artery beyond the tumor, we shall find, in either of these cases, that there are important branches going off between the tumor and the ligature, by which probably a current of blood will be constantly kept up through the aneurismal tu-

mor. In a case of aneurism of the femoral artery, for instance, we shall hardly be able to tie the trunk of the vessel above the profunda; and if that artery remain between the tumor and the situation in which the ligature is applied, we should expect, from its magnitude, that an active circulation would be kept up in the aneurismal tumor after the operation—which would consequently fail. In aneurisms of the axillary artery there is a variety of large branches seated near the tumor—so near that we cannot get between them and the aneurism to apply the ligature, and there would be the same circulation of blood through the tumor as if no ligature were applied. The two cases, therefore, seem to me to be very different in point of principle—viz. those in which aneurisms are seated in trunks that give off no branches, and those that are seated on trunks where numerous branches are given off, and where we cannot apply a ligature at the part most remote from the heart, between the tumor and the origin of those branches. Still, as I have already said, the question is one of experience; and until the experiment has been tried, we cannot venture to determine that this operation of applying a ligature on the trunk of an artery beyond the tumor may not be advantageous and effectual, even as regards the femoral and axillary arteries.

That the obliteration of the inferior end of the artery does not necessarily lead to the cure of aneurism, I have had an opportunity of observing; indeed I have mentioned to you an instance in which the inferior extremity of the femoral artery had become obliterated in consequence of the pressure of an aneurismal tumor, and yet the tumor went on increasing. There the natural process of the disease produced the same effect as is proposed to be accomplished by the application of a ligature beyond the tumor; yet the increase of the tumor was not apparently suspended by that event. The impression upon my own mind, I acknowledge, is, that this operation is not likely to succeed on the femoral or axillary arteries, although it has succeeded on the carotid.—There would be great difficulty experienced in performing the operation. The aneurismal tumor often advances considerably up the trunk of the artery, beyond the part where the artery has yielded; so that we cannot get near enough to the actual point where the artery has given way to apply the ligature close to it, and consequently collateral branches would be left between the aneurismal tumor and the ligature, which would keep up the circulation in the way I have mentioned. You will remember, however, that the question of performing this operation can only arise in cases of a very serious kind, where the position of the aneurismal tumor is such as to preclude the performance of the ordinary operation, so that

the patient is left, probably, to almost certain death, unless some attempt of this kind be made. Under such circumstances it may be preferable to try a doubtful expedient rather than to leave the patient without an effort to save him. At all events, you understand that the observations I have now made upon the subject are general; that they do not proceed from a knowledge of the subject derived from my own experience, because I have not seen the operation performed: and in all matters of this kind we must distrust general reasoning; for we often find, when we come to try, that the result is totally different from that which we had previously anticipated.

Varicose Aneurism.

There is a peculiar modification of aneurism, respecting which I have a few words to say,—it is what is called *varicose aneurism*. It is produced by a wound, generally, of the brachial artery in venesection; and the peculiarity arises from this circumstance. The artery is wounded through the vein; the coats of the artery and the coats of the vein become connected and closely adherent to each other: at the same time the wound or aperture remains between them, so that the blood, instead of flowing out into the cellular membrane from the artery, as it does in ordinary circumstances, passes immediately into the vein; and thus the vein becomes in a manner the aneurismal sac, and an enlargement of the vein takes place similar to *varix*;—hence the term *varicose aneurism*. The condition of the part ultimately is that of a tumor that you feel at the bend of the arm, which pulsates, receiving its impulse from the blood of the artery. In order to produce this effect, of course the external wound of the vein must close, as it does ordinarily after venesection.

Now the swelling generally proceeds to about the size of a walnut or a pigeon's egg, and then remains stationary. The blood passes through the continuous veins in their ordinary course; and inasmuch as these veins form an outlet to the distended varicose part of the vessel, its enlargement is limited. No doubt this would enlarge much more considerably, and ultimately proceed to bursting, but that the blood flows from the part in the natural course of the circulation in the veins. In this state the complaint remains stationary,—it does not acquire a great size, and no operation is necessary for it. The limb perhaps is rather weakened, but in other respects the patient suffers no particular inconvenience. There is a peculiar character belonging to the affection,—a kind of vibration that is communicated to the hand and to the ear, produced by the passage of blood from the arterial trunk through the small opening into the vein. The sensation is almost the same as

that communicated to the hand by the vibration of the cord of a musical instrument; and it has been particularly described, by all who have witnessed this affection, to be what is called a *whizzing* noise—a small thrill or vibration. It is not only felt in the swollen part of the vein, but it also extends along the course of the vessel up the arm.

[Mr. Lawrence here exhibited a drawing of varicose aneurism, taken from the arm of a young gentleman in whom the artery had been punctured about five years before the drawing was taken.] The lecturer continued—He was labouring under very serious pulmonary inflammation, and was bled in consequence of it. Nothing particular was observed at the time: the wound was closed when the requisite quantity of blood was taken, the arm was bound up, and the surgeon who performed the venesection was not aware of any thing unusual. It happened in the course of the night that the patient felt the arm very uneasy, and mentioned that circumstance to the surgeon when he called next day, who took off the bandage and examined the part; and then, according to the description of the patient, he saw a swelling that was *beating* faintly in his arm. The surgeon no doubt saw this also, for he applied a compress upon the tumor, and bound it firmly—probably with the idea of putting a stop to the affection. However, the pressure could not be borne by the patient, and it was necessary to loosen it; but even then it was applied as tightly as the feelings of the patient would admit of. That this mode of proceeding did not prevent the occurrence of varicose aneurism was clear, from the present state of the limb. The patient was much reduced, and confined to his bed, so that he was placed under favourable circumstances for effecting a cure of his aneurism. In the course of five months the tumor had acquired the magnitude represented in the drawing, and from that time there was no increase in its size. The tumor was about as large as a pigeon's egg, of a light bluish tint, soft, and when the hand was put upon the artery the tumor disappeared; that is, the blood passed out through the veins. It was quite soft, so that you could press the blood out at any time. No laminated coagula were deposited; and there was, in this instance, that marked degree of vibration which I have already mentioned as characterizing this affection. Besides the oval soft swelling which is here depicted, there was an enlargement of the veins, particularly of the basilic, extending three inches up the arm. It was tortuous, and about the size of the finger. It is clear that the swelling of the vein at the bend of the arm, and the enlargement above, were owing to the injection of blood from the artery, and not to the impediment of the return of the venous blood; because otherwise the vessels would have

been enlarged below the situation of the wound, whereas they were enlarged above that situation.

I should observe, that in this case no pulsation can be felt at the wrist of the same arm. The diversion of the main current of blood at the bend of the elbow prevented the pulsation at the wrist; and in conformity with that circumstance, the circulation appears enfeebled in the limb generally, so that the limb is livid compared to the other: it is colder and not so strong as the other arm.

LECTURE XLV.

Application of Ligatures to certain Arteries, as the Internal Iliac—Subclavian—Innominate—Aorta.—Wounds of Veins—Phlebitis.

I SHALL have occasion, gentlemen, to shew you the mode of exposing and tying those arterial trunks which are most frequently the seat of aneurism, and therefore I shall not at present enter into any further remarks respecting particular aneurisms, except just considering the propriety of tying some three or four of them, respecting which the opinions of the profession are perhaps not completely decided. The external iliac artery has been frequently and successfully tied in cases of aneurism of the femoral, seated near the crural arch. There is one case on record in which it is said the internal iliac has been tied for aneurism of the gluteal; and I believe in one case the common iliac trunk has been tied. I do not pretend to say that a ligature cannot be applied to these vessels; but I must represent to you that I should think the operation extremely difficult, and I should attempt it myself with great anxiety, and under considerable doubt as to the possibility of effecting the object.

The main trunk of the artery of the upper extremity may be tied as high up as the *external edge* of the scalenus muscle: a ligature has been applied to it in this situation in various instances, and sometimes with success. The question is, whether it can be tied on the *internal edge* of the scalenus, or whether the trunk of the arteria innominata can be tied on the right side? I should think it preferable to tie the trunk of the arteria innominata, rather than to attempt placing a ligature on the subclavian artery at the inner edge of the scalenus. The arteria innominata is seated behind the first bone of the sternum, and at no very great depth from the surface of the body. In the dead subject certainly it is not very difficult to cut down upon and place a ligature round it; but in the living subject two questions arise—*first*, whether those parts that are supplied by the right subclavian and right common carotid arteries (branches of

the innominata), are likely to receive an adequate supply of blood when the arteria innominata has been tied!—*secondly*, whether the arteria innominata will unite and become consolidated as other arteries do after the application of a ligature? If we place a ligature upon the trunk of the arteria innominata, and throw an injection into the aorta, where it arises from the left ventricle of the heart, we shall find that the injection will fill the vessels of the right upper extremity and the right side of the head; in truth we know that there are very large communications between the arteries in the interior of the head and between those of the right and left side, and probably these communications alone are sufficient to maintain the circulation under the circumstances that I have mentioned. So far as the dead body goes, this experiment is decisive. In relation to the same question in the living subject, the arteria innominata has been twice tied. It was tied in the first instance by Dr. Mott, of New York, and the case was so far successful, that at the end of about three weeks the patient recovered to such an extent that I believe he walked out; however, hæmorrhage came on, and ultimately the case terminated fatally. It was found, that although the right extremity, and right side of the head had been supplied, the process by which the union and consolidation of the arteries ought to have been effected had failed, so that when a probe after death was introduced into the trunk of the arteria innominata, it passed out through the open extremity of the artery in the wound. Professor Graëffe, of Berlin, has once tied that artery, and his patient also seemed to be cured: it was considered, in fact, that the case had succeeded, but the patient died of hæmorrhage on the sixty-first day after the operation. At present, therefore, it may be considered doubtful how far we ought to attempt to tie the arteria innominata. I should, for my own part, however, prefer doing so to attempting to tie the subclavian, on the inner edge of the scalenus; nay, I do not know whether we are not as likely to succeed as by passing a ligature on the artery at the external edge of the scalenus; for there are several large arteries coming off from the trunk of the subclavian, and proximity to a large artery is a disadvantageous circumstance in reference to the effect of a ligature, because it impedes the formation of a coagulum—one of those natural processes which favours the consolidation of the artery after ligature.

I have already mentioned to you that in two instances a ligature has been placed on the abdominal aorta; and it is proper to consider the question whether it is right, under any combination of circumstances, to place a ligature upon that vessel. The only case in which it can be matter of question,

is in an aneurism of the external iliac artery, reaching high up into the pelvis. Of the two instances that I have related, one has been already published, in which the abdominal aorta was tied by Sir Astley Cooper; the other was read this season before the Medical and Chirurgical Society, and will be published in the forth-coming volume of their transactions; it was performed by Mr. James, formerly a pupil here, and now one of the surgeons of the Exeter Hospital. The operation was performed by making an incision into the linea alba, through the muscles and integuments of the abdomen, turning aside the bowels feeling the artery where it lies on the front of the vertebral column, and passing a ligature behind it. There can be no great difficulty in doing this; for when you are lying in bed, if you make the experiment on your own person, you will find that you can trace the abdominal aorta from the chest into the two iliacs. There is no great quantity of parts to cut through, and the performance is not difficult.

The reason of practising this or any other operation, is to put a stop to a disease that is likely of itself to terminate mortally; or, if we cannot actually put a stop to, and cure the disease, at least to prolong the existence of the patient. I cannot say that so far as the two cases which I have just mentioned go, or so far as I should anticipate from reasoning *à priori*, as to the probable result of such operations, that a ligature of the abdominal aorta seems to me likely to accomplish either the one or the other of these purposes. I cannot say that we should expect from it a cure of the aneurism situated under the circumstances that I have mentioned; and I think it much more likely to help the patient on his journey to the other world than to retard his progress. It therefore seems to me that, at present, it is one of those operations which had better not be performed.

Wounds and Injuries of Veins—Phlebitis.

Wounds of veins, like those of arteries, are attended with a flow of blood, or hæmorrhage. Venous hæmorrhage is much less formidable than that which proceeds from arteries; indeed, under hardly any circumstances should we entertain much alarm at the flow of blood that takes place from a vein, for we find, in general, that the natural powers of the constitution seem adequate to resist this process. The flow of blood from a vein ceases if left to itself; coagulum forms in the orifice of the vessel, and the opening becomes closed. If this does not take place, pressure on the opening is sufficient to arrest the bleeding, and that gives occasion to the formation of a coagulum within the vessel, which will permanently stop the hæmorrhage.

Pressure is the method which we should trust to for arresting hæmorrhage, when it takes place from a vein; and we should not,

unless we actually cannot avoid it, think of applying a ligature.

Veins very easily become inflamed; and the inflammation of a vein, when once produced, is a very serious occurrence—in many cases terminating fatally. The application of a ligature is one of the exciting causes which, in many cases, has led to the inflammation of a vein, which has had a fatal termination; unless therefore under circumstances of urgency, in consequence of the magnitude of the vessel divided, or in consequence of the failure of other means in arresting the bleeding, we should not think of applying ligatures in the wounds of veins. We divide a great number of veins, as well as arteries, in the amputation of a limb—the thigh for example, but we do not find it necessary to apply ligatures for that. In fact, for the most part, veins are furnished with valves, which prevent them from bleeding. Not uncommonly, however, we experience from the femoral vein so profuse a hæmorrhage, as to render it necessary to adopt some means for stopping it. The deep-seated veins are not so well furnished with valves as the more superficial; and if the femoral vein bleed freely, it may be well to apply a ligature upon the orifice, without drawing the knot tightly, and thus to stop it during the time that you are tying the other bleeding vessels; and then, if you take off the ligature, you will probably find that the vein will not bleed. But if, after securing the other vessels, we find that a large stream of blood still issues from the femoral vein, we seem to have no other course except that of tying it. I have had occasion many times, in the amputation of the thigh, to tie the femoral vein, and I cannot say that I have seen any unfavourable result from it; yet it ought never to be resorted to, except under circumstances of absolute necessity.

The opening which we make into a vein at the bend of the arm, for the purpose of venesection, is a wound of a vein; and you know very well that simple pressure, and that not considerable, suffices to stop the efflux of blood from it. It is not my intention, and I do not deem it necessary, to enter into a description to you, of the mode in which a vein is to be opened in venesection. I may observe, however, that though it is the first operation that is usually learnt, and though most of you understand, and are capable of performing it, it is perhaps not one of the easiest of surgical operations to perform neatly, effectually, and safely. When I say *neatly*, I speak of opening a vein and receiving the blood that flows from it, without letting it escape over the dress of the patient, or the apartment in which the bleeding takes place; when I speak of doing it *safely*, I mean performing it in such a way as to run no risk of injuring the artery, which is seated near one of the veins in which the

bleeding usually takes place ; and when I say *effectually*, I speak of closing the wound, and applying such a bandage to the arm, and directing the patient to employ such means, as will prevent the occurrence of inflammation ; for I must observe to you, that in many cases the simple wound inflicted in phlebotomy has been the exciting cause of fatal inflammation of the vein. This operation, therefore, although regarded as so simple, that one the least initiated in the profession may perform it, yet when you come to consider the consequences to which it sometimes leads, is not to be deemed so very unimportant.

Inflammation of a vein has received the technical name of *phlebitis*. $\Phi\lambda\epsilon\psi$ is the Greek for vein ; hence the term *phlebitis* is merely the word, with the termination *itis* added to it, to denote inflammation. When inflammation occurs in a vein, the patient, in the first instance, is admonished of its existence by uneasiness in the part, and a sensation of stiffness on motion ; and these are gradually augmented until the patient perceives considerable pain in the situation of the inflamed vessel. The vein swells, the coats become thickened, the inflammatory action extends to the cellular substance, which becomes the seat of effusion ; and thus the vein itself, and the part in which it is seated, undergo a general tumefaction. When the inflamed vein is seated superficially, and when more than one vein are involved in the affection, we shall find a considerable swelling of the part, and the increased action extends to the skin, which then becomes red. The skin is red, tense, and considerably painful ; and this change extends downwards along the fore-arm, and upwards along the arm. When these changes take place in the veins, the orifice (in the case of phlebotomy) from which blood has been taken, instead of having united, is found to have separated, or as people commonly call it, *festered*. There is the appearance of matter in the opening of the vein ; and after the inflammation has existed some three or four days, we shall find that a thin matter, which is sometimes reddish from an admixture of blood, escapes from the opening. Sometimes it appears like pretty good pus, but more commonly it is thin, and has a reddish tint ; and sometimes it flows in considerable quantity. When the parts are thus swelled, and the skin red, there is, of course, considerable tenderness on pressure, so that when we touch the part it will give the patient pain. In conjunction with these local changes, we find a considerable febrile disturbance of the system taking place. There is an excitement of the pulse, which becomes more full and frequent—sometimes being as much as 130 or 140 in a minute ; the tongue is white ; there

is frequently sickness, nausea, and vomiting, a costive state of the bowels, and thirst. Together with these symptoms there is usually a considerable degree of anxiety and restlessness: the patient cannot sleep at night, but is very uneasy, tossing himself about ; and likewise feeling very uncomfortable during the day-time. There is generally an uneasy sensation about the præcordium ; and the patient is apt to be low-spirited, entertaining gloomy apprehensions respecting the issue of the case. As the disease advances, something like delirium comes on ; yet, if you speak to the patient, and rouse him, you generally get an answer : you hardly find any thing very decided in the shape of delirium. Frequently there is a remarkable degree of irritability about the patient ;—a slight noise, or a slight impression of any kind, produces a considerable effect on the nervous system. The patient is very fretful, and very easily excited. The skin generally assumes a sallow, and often a yellowish appearance ; the features become sharp and contracted. The febrile disturbance does not long assume an active inflammatory character. That part of the disease soon passes over, and a condition more allied to the typhoid state comes on ; the tongue becomes dry and brownish ; there is great prostration of strength ; sordes appear about the mouth ; and the general condition of the patient assumes the character which is denominated *typhoid*. In this state we very frequently find symptoms of active inflammatory affection shewing themselves in some internal or external part of the body: sometimes inflammation occurs in the chest or abdomen—sometimes in some of the joints of the body. Under the continuance of this general febrile disturbance, and these external or internal inflammations, the patients sink, dying at various periods of time from the first occurrence of the symptoms. A case is mentioned by Mr. Hodgson, in his work on diseases of the arteries and veins, in which inflammation of the femoral vein came on in consequence of a ligature applied upon the saphena, where the patient died on the fourth day. I have seen cases where this affection has terminated fatally, where the fatal event has been protracted to seventeen or twenty days.

When we come to examine these cases after death, we find, if the inflammation of the vein be in a very early stage, that the coats of the vessel are thickened, and that its internal lining is red ; the cellular membrane surrounding the vein being infiltrated with serum. At a latter period, we find these changes taking place to a more considerable extent, so that the cellular membrane of the region in which the affection has taken place, is considerably thickened ; partly perhaps by a deposition of lymph, and partly by serous

effusion. The coats of the inflamed vessel are considerably thickened and indurated, and the cavity of the vessel is lined by a stratum of lymph, which occasionally adheres to its sides, and, when we cut the veins open, gives it an appearance as if the tube was plugged up with the lymph or coagulated blood. When we examine the surface of this adventitious covering, towards the vein, it seems like an effusion of lymph closely connected to the vessel, but the surface towards the centre of the vessel has somewhat the appearance of coagulated blood; and we have various gradations of these appearances—some parts exhibiting the yellow appearance of effused lymph, such as would take place from a serous membrane in a state of inflammation, and the other parts often exhibiting the reddish appearance, more like a coagulum of blood.

[Mr. Lawrence illustrated this by a specimen of the vena cava, which was completely covered by a reddish kind of fur. He also exhibited a volume of the Transactions of the Medical and Chirurgical Society, containing two or three figures representing the appearances of this affection; one of which was that of an external iliac vein, which was filled up with this deposition; a second figure represented the femoral vein, filled up with coagulum of blood; a third figure was that of the vena cava, exhibiting the affection in a more advanced state, where there was a regular deposition of lymph.]

These changes extend to various distances along the vein, and in the case of inflammation excited by a puncture in venesection, if it should occur in the basilic vein, for instance, we should probably find it reaching as far as the termination of the basilic in the axillary vein. If it occur in the cephalic vein, it may reach a few inches higher up, sometimes to the neck, extending to the subclavian vein, as far as the termination of that and its junction with the internal jugular. These changes also extend downward, in the course of the circulation. Those veins that are seated on the fore-arm will become thickened, hardened, and will contain either lymph or pus in their interior, as far as the hand; for I should mention that it may happen that the veins, instead of being plugged up by this deposition of lymph or coagulated blood, are sometimes thickened, or rendered rough and irregular on the inside, and contain pus in a fluid state; so that the inflammation which attacks the venous coats, and particularly affects the internal lining, produces either a deposition of coagulated lymph or the formation of pus.

If we examine them at a later period, when the inflammation has been reduced, we shall find that the lymph is absorbed; that the veins have their cavities obliterated;

that they are reduced either into the state of solid, impervious cords, or else, when we cut them open, we find that they are filled by a kind of adventitious membrane, something like the adhesions that form between the contents of the abdomen and the parietes of that cavity. That is the appearance which the veins will assume when the inflammation has gone through its stages and has been cured, or ended naturally.

But then in fatal cases we find various other affections of important parts which lead to the fatal event; for you will easily understand that inflammation of a portion of a vein considered in itself, would not be sufficient to destroy the life of the individual. If it be seated in the basilic or cephalic vein of the arm, and no other parts be affected, you cannot suppose that the patient will lose his life from it; but phlebitis terminates fatally, in consequence of its secondary effects, that is, from effects which the inflammation in a vein produces on other parts of the economy. These other effects consist of inflammation of one or other of the serous membranes, sometimes affecting several of them simultaneously; inflammation of the pleura ending in the deposition of a sero-purulent fluid in the cavity of the thorax; inflammation of the lungs with a deposition into their texture of a kind of imperfect purulent fluid—that kind of deposition in the texture of the lungs which is found to take place frequently after serious external injury, a deposition which we cannot exactly call lymph, and which we cannot correctly call pus, but which appears to be something between them—a sero-purulent deposition: sometimes a similar deposition occurs into the texture of the liver, or some other of the viscera of the abdomen;—inflammation of the pericardium, sometimes of the muscular texture of the heart, with depositions of the nature that I have alluded to; inflammation of some of the joints—of the synovial membranes, with effusion of pus into one or more of their cavities. These are the kinds of changes which occur as the secondary consequence of phlebitis, and which assist in producing the unfavourable termination in those instances which end fatally.

LECTURES ON SURGERY,

Delivered at St. Bartholomew's Hospital,

BY WILLIAM LAWRENCE, F.R.S.

LECTURE XLV.

[Concluded from the preceding page.]

Phlebitis, continued; its Pathology and Treatment—Paris.

Two or three years ago I had several cases in the hospital, all occurring nearly together, in which phlebitis ended fatally, and in which I had an opportunity of observing the principal appearances that were produced in consequence of this affection. In one of these instances, which was that of a patient who came to the hospital with an old ulcer of the leg—a large man, in whom the part had become inflamed, and the ulcer had extended considerably in consequence. It was necessary to bleed him, and to keep him low, and under that treatment the leg got well. But the wound made by the lancet in venesection did not unite; it festered, and in fact phlebitis took place. After the inflammation had existed for a few days, the knee-joint of one side swelled considerably, and this swelling extended to the thigh of the same side generally; then the opposite shoulder-joint swelled, and at length the patient died. On examination, we found that the inflammation of the vein seemed to be in a natural course towards a cure, but the synovial membrane of the affected knee was inflamed in the highest possible degree; the whole surface of the joint was a bright red colour, and its cavity was filled with pus. There was a deposition of pus generally into the cellular texture of the thigh, beginning immediately on the outside of the knee joint, running in the interstices of the muscles, and affecting the cellular membrane of the entire limb. There was a similar deposition of pus surrounding the shoulder joint of the op-

posite side. I had a case some time ago under my care, at Bedlam, and the patient, who was in a state of mental derangement, had been sent from the country. He was bled in the arm before he set off, and it seems that they took no particular care to bind up the arm properly before they sent him on his journey. When he arrived at the hospital, although he was in a state of mind not to give a clear account, yet he said that he had pain in the arm. On examining him, I found that he had been bled, and that the limb had been confined tightly from the means adopted to restrain him on the journey. There was the impressure of a cord, or something used in confining him, that had made a visible impression on the arm. Swelling was present, besides this painful state of the arm; and thus it was pretty clear, though the man could not give a good account of himself, that inflammation of the vein had been brought on, partly in consequence of venesection, and partly in consequence of the external irritation from the mode of confining him. Means were adopted for reducing the local inflammation, which had a very favourable effect; the arm became considerably less swelled, the redness disappeared, and, in fact, before the patient died, the arm had assumed pretty nearly its natural size and appearance; however, there was considerable febrile disturbance, a white tongue, want of sleep, a great degree of restlessness, and, as the affection went on, a peculiar difficulty of breathing seemed to join itself to the other symptoms. The man occasionally complained (but we hardly knew whether to ascribe it to actual sensation, or the state of mind he was in) that he had hot air in his throat; and, indeed, he seemed to have a sensation about the throat that was particularly painful. He died. I examined the case after death, and I found that the affection of the vein extended from the basilic into the axillary vein, and along the trunk of this and the subclavian as far as the termination of that trunk, and the junction of

the internal jugular, where it abruptly ceased; but in the original seat of the inflammation the affection seemed to be pretty much on the decline. The chief morbid changes in this case were found in the heart and pericardium. Within the pericardium there were several ounces of thick, turbid, fluid serum, with a good many flakes and much purulent matter mixed with it. The whole of the pericardium covering the heart, and the reflected portion of this membrane, were highly inflamed—more so than I had ever seen them before. The minute vessels of the membrane were excessively injected, so as to give the whole of it a bright red colour; and in one part there was ecchymosis under the membrane. The whole of the left ventricle of the heart had a bright scarlet colour, in consequence of the injection. At one part of the left ventricle, in the midst of this bright red, there was a yellow spot observed, which might be about the size of a sixpence. On making an incision to examine the fibres of the heart, I found them broken down, and mixed with a yellow purulent fluid. It was the same kind of purulent deposition in the muscular substance of the heart which is so often found, in similar cases, in the substance of the lungs or liver.

It is an interesting inquiry in these cases how the inflammation of the vein leads to the effects that I have now been describing? How the inflammation of the vein, in the first instance, excites that febrile disturbance of the system which is a marked circumstance in cases of phlebitis? And how this inflammation of the internal parts, quite remote from, and apparently unconnected with the original seat of mischief, become superadded to the affection, so as to lead to the fatal termination?

An idea has been entertained, that the inflammation of the vein is propagated along the lining of the vessel to the heart. This, however, does not accord with what we find on examination after death. We sometimes find that the inflamed portion of the vein does not extend very far from the seat where the external irritation has been applied to it; and in all instances we find it ends short of the heart. I do not know of any instance in which there is reason to suppose that the inflammation has been actually communicated to the heart; on the contrary, in the cases that I have mentioned, where it reached as far as the termination of the internal jugular, the vein from that point—the superior vena cava, was perfectly healthy. In other instances it has not reached so far.

It has been the opinion of some that the mischief in question arises from the pus which is formed in the inflamed vein passing into the circulation. This opinion has been given by M. Breschet, in an article on phlebitis, in the *Dictionnaire de Medecine*. The same opinion has also been given by Mr.

Arnott, in an elaborate paper on Inflammation of the Veins, contained in the XVth volume of the Transactions of the Medical and Chirurgical Society. Both these gentlemen advert to the effect produced by injecting pus, or other acrid substances, into the veins of living animals; and they say, that in these instances the purulent secretion produced from the inflamed vein passes, in the course of the circulation, into the system generally, and thus excites the mischief.

With respect to the causes of phlebitis, we find, in most cases, that it is traceable to some external injury, or some direct external application: thus the wound that is inflicted on the vein in phlebotomy has, in many cases, produced this affection; and it happened in one instance, that terminated fatally, three or four years ago, in the hospital under my care. This was a case in which a young woman had received some injury, for which she was bled in the arm. She was by occupation a weaveress, and she went to her work after the phlebotomy had been performed. She continued to employ her arm in weaving; but on the second day after the bleeding, inflammation of the vein came on. This female, on the following day, was received into the hospital, labouring, in a marked degree, under all the general and local symptoms of phlebitis, and she died from the purulent deposition in some of the joints; but I was not allowed to open the cavity of the chest, or the abdomen, so that I cannot exactly tell what state these were in. I saw phlebitis arise in a gentleman, under my care, on whom I performed a slight operation. I bled him in consequence of symptoms that ensued after this operation. He had come from India, but was a young man, and apparently healthy. However, the wound in the arm led to inflammation, and he died in consequence of it. And I may here state, that in performing operations on persons coming from India, sometimes a fatal disturbance arises where we should not expect that effect; so that probably, from the diseases that Europeans experience in those climates there is some unfavourable effect produced on the system which renders them less able to undergo operations than the persons that we ordinarily have to deal with in this country. This explained to me a circumstance that I had sometimes been rather puzzled about—that individuals should be advised to go and get operated upon in England. I suppose that the surgeons in the East Indies find that operations do not turn out very favourably there.

Other external injuries applied to a vein are capable of producing serious inflammatory affection of the part. In consequence of the changes that take place during parturition, and of the mode in which the veins of the uterus are exposed, by the separation of the

placenta, as well as in consequence of the effects produced by portions of the placenta remaining adherent, inflammation will arise in the veins of the uterus, and will be extended from them to the internal iliac, and even to the external iliac and femoral veins, and thus become the source of a serious affection, called phlegmasia dolens; or if propagated to the vena cava, may lead to fatal consequences. The researches of Dr. Lee, of Argyll Street, on this subject, have contributed to place this subject in a clear light. His remarks upon it will be published in a forthcoming volume of the Transactions of the Medical and Chirurgical Society. It seems, from what he has stated, that inflammation occurring in the veins of the uterus, and propagated from them to the internal and external iliacs, and some other veins, is the source of some of those obscure affections which have been recorded under the general name of puerperal fever. It is not unlikely that in compound fracture, and other serious injuries, inflammation of veins may arise; and thus that phlebitis may, without our being aware of it, have a greater share in producing some of the consequences of these injuries than is supposed. This point, however, is not yet sufficiently investigated.

The next point of our inquiry is, as to the treatment of this affection. I believe the best plan of treatment consists in applying, as early as possible, leeches, in large number, over the veins in which the inflammation has originated: in attempting by the local abstraction of blood—and by such other means as are likely to reduce inflammation—to overcome the inflammatory disturbance in the parts.

The considerable febrile disturbance of the system which exists in the early period of the affection, leads us, in many cases, to infer that general bleeding would be of service; and, accordingly, many patients have been bled freely from the arm in cases of phlebitis. The febrile disturbance is generally lessened by such bleeding; but although the symptoms are lessened for a time, I think we do not in general find that any corresponding influence is produced in putting a stop to the affection. The symptoms come on again, and soon the period of active inflammation passes by, and a condition, of a typhoid character, comes on, in which general depletion is not only unnecessary, but would be absolutely prejudicial; indeed, in the advanced stage of the disease, where you have great anxiety and restlessness, and where there is a great degree of irritability, with depression of the nervous system—where the tongue begins to become brown, with urgent thirst—we are at a loss to know what to do, for none of the means that we usually adopt are of much advantage. I have given mercury pretty freely in that state without seeing it do much

good. I have tried narcotics, such as hyoscyamus, opium, and other sedatives, perhaps with a little benefit, but without much effect in mitigating the progress of the disease; for when the disease has gone to a certain point, and these internal affections which I have alluded to have taken place, we seem to have little power in controuling the disorder. The intractable nature of the affection, therefore, holds out a strong motive for adopting every means in cases of injury, or wounds of veins, that are calculated to avert the occurrence of inflammation, and is a reason for adopting, in the early period of the affection, when the inflammation first comes on, those local anti-phlogistic means—leeches, and so forth, that are calculated to lessen the inflammation of the part; for if we neglect these two points, and allow the disease to become fully developed, the patient in most instances is lost.

Varix.

The veins are subject to an affection which is denominated *varix*, that is, enlargement of the vessel, with thickening of its coats, and this occurs chiefly in those situations of the body in which the return of the blood takes place contrary to its gravity, particularly in the lower extremities. In veins that are thus seated, not uncommonly attacks of inflammation come on; the coats of the vein become thickened; deposition takes place in them; and thus they become very considerably enlarged in size, and assume a tortuous and irregular course. This affection often exists for a great number of years, and sometimes will extend to the whole of the veins of the lower extremities, which leave an irregular knotted appearance, rising above the skin, and projecting at all parts of the limb. You are often surprised to see such general changes of the superficial veins of the limb, and the patient apparently experiencing very little inconvenience from it. Frequently, however, these varicose affections of the veins are the source, not only of inconvenience, but even of danger. Such diseased veins are of course more liable to the occurrence of inflammation than others. The distention sometimes becomes very considerable; the coats of the vessel get thin, and at a certain point they give way and break; and thus a large quantity of blood may be lost from the rupture of such veins. The swelling of the veins, particularly under considerable employment of the limb, is attended with great pain and inconvenience, and limits the patient very much in his exertions in walking, and so forth.

If the varicose veins become very actively inflamed; if they become enlarged and hardened, and the skin over them red; and if it is painful to the touch, we must treat them as we should inflamed veins under any other circumstances. We must take blood

from the part, and employ other means necessary to reduce the inflammation. When the inflammation has been reduced, the best mode of treating varicose veins is by pressure—pressure, by means of a well applied bandage, or adhesive straps, or soap plaister. These are the various modes by which pressure is to be applied to the limb; and they will often limit the progress of the affection, keep the veins within a certain size, and enable the patient to use all ordinary exertion without inconvenience.

It is a question whether we can, with any safety, proceed farther in the treatment of varicose veins of the limb than I have mentioned; whether we can do more than apply leeches, or other means calculated to reduce inflammation, and then use pressure: in other words, whether we can, with safety, adopt means for effectually diminishing the size of the veins? For this purpose, it has been recommended at various times to tie the trunk of such enlarged veins; to make a division of the trunk, and actually to cut away the vascular enlargement. If the main trunk connected with the varicose vessels be divided or tied, certainly a considerable diminution of this enlargement of the veins will ensue. But here you must recollect the danger that will arise from the application of a ligature to a vein under such circumstances—a vein by no means in a healthy state. You must recollect the danger of exciting by such an operation inflammation of the vein, (phlebitis), and, in truth, patients have died in many instances in consequence of the application of ligatures to veins for this purpose. Individuals who have been in good health, and have had nothing but this local inconvenience, that might easily, by safe means, have been kept within a moderate compass, from a desire of radically getting rid of it, have had the operation performed, and have died in consequence. This has taken place so often that no one would now think of adopting the plan of ligature in these cases. Another mode of attempting to cure the affection has been by cutting away a part of the enlarged vein—but this operation also has terminated fatally in many cases. The only safe proceeding of this kind, and even that I should not deem absolutely safe, is the one proposed by Mr. Brodie; it consists in dividing the varicose vein under the skin; making a very small opening with a slender and narrow knife, which is introduced at the side of the vein. It is a curved knife, cutting on the convexity, very narrow pointed; it is introduced at the side of the vein, and carried, with the flat surface, horizontally under the skin, between it and the vein. Then the knife is turned, so that the convex cutting edge is towards the vein, and drawn out, so that the vein is incised under the skin, no further opening being made than is just sufficient to

introduce the narrow knife into the skin at the side of the vein.

In general this operation is not attended with so much risk as accompanies either the excision of a part of the varicose vein, or the application of a ligature to it. In those instances, therefore, where it is necessary to do any thing at all in the way of operation, this is the preferable mode. But the great danger which attends all modes of wounding veins, particularly those which are in this diseased state, has led, I believe, pretty generally to the abandonment of attempts of that kind; and surgeons are now satisfied with the means that I have already described to you, as of a more safe character for the treatment of this affection.

LECTURE XLVI.

OSSEOUS SYSTEM.

Injuries of Bone—Exfoliation—Fractures.

GENTLEMEN,—Although the bones appear at the first view so different from the soft parts of the body, the organic elements which compose them are essentially the same. Cellular structure, arteries, veins, absorbents, make up the basis of composition in both instances. Hence we find that bones exhibit the same living phenomena, whether in health or disease, as the soft parts; they are equally capable as the soft parts of *repairing injuries*; they go through the processes of inflammation, swelling, suppuration, ulceration, granulation, mortification. They are also susceptible, like the soft parts, of various *organic* changes; thus they exhibit sarcomatous, steatomatous, cancerous, fungoid, and melanoid changes of structure. The various diseased actions, like the healthy processes of nutrition, absorption, and so forth, are essentially the same in the bones as they are in the soft parts of the body—the only difference is in the form or appearance under which they present themselves, a difference which is obviously referrible to the difference of structure in the two instances. The chief character which distinguishes both the healthy and the morbid processes that occur in the bones from those that take place in other parts, is the comparative slowness with which they are affected. You find that all the processes of disease, as well as of health, go on much more slowly in bone than in the soft parts.

From the hardness of their structure, bones are hardly susceptible of that kind of injury which is so frequent in the soft parts from incised wounds, yet they are often exposed in wounds, and we have an opportunity of seeing the mode in which the effects of such injuries are remedied. The bones are necessarily divided in the operation of ampu-

tation;—when the thigh, for example, is amputated, we have the bone to saw through. We place the soft parts over the bone, and these, perhaps, unite by adhesion; they cover the bone, they become adherent to it, and the wound goes through just the same process that it would have done if it had consisted of a wound of the soft parts only. We see no circumstances which indicate to us any peculiar character from the division of bone in such an instance. It may happen that such a wound does not unite by adhesion; although the soft parts are brought together, they do not heal, but suppurate, and they subsequently unite by granulation. Under these circumstances, we shall see that the bones produce granulation as well as the rest of the wound. Those red roundish prominences to which the term of granules is given, spring from the surface of the bone generally, and they unite with the granulations which are produced by the surrounding soft parts, and enter into the composition of the common cicatrix. It may happen under such circumstances that the soft parts retract, and the bone protrudes from the wound, that is, a certain portion of the bone protrudes and becomes denuded of the investing membrane, or periosteum—it perishes, and then it is separated from the sound part of the bone by a process which I shall presently mention to you.

It is not uncommon to have the bones exposed in wounds. A bone may be exposed, but still covered by its periosteum, and if the soft parts are brought together over it, the process of adhesion will be just the same as if there were no bone in the case. The bone, however, may be completely laid bare, that is, it may be denuded—the periosteum actually detached from the bone, this being either not injured at all, or but superficially marked by the injury which has been inflicted. Under such circumstances we lay the soft parts down, we bring the integuments together, and approximate them over the surface of the denuded bone. They will probably unite by adhesion, cover the bone, and the process of union will go on just as if the bone had not been exposed. It occasionally happens, however, that the parts do not unite, that the wound becomes an open one, and granulates, and then a certain surface of the bone is exposed—that is, in common phrase, *denuded*. We see a portion of bone of a whitish or yellowish appearance, and it appears to us as if it were dead. If this portion of bone be not considerable, and if the surface of the wound be kept moist—if it is not exposed to the atmosphere so as to be allowed to become dry, we find the bone does not assume actually a dead white colour, but there is a kind of semi-transparency belonging to it—it retains something of a pinkish hue, and after some days have

elapsed, probably numerous little pinkish spots appear on the surface of the bone, and these gradually rise till they assume the appearance of granulations, and in fact they are granulations springing out of the denuded surface of the bone. In this way we shall find that the exposed surface of the bone will be gradually covered by a production of a granular kind, very similar to that which takes place from the soft textures of the body, and the granulations which thus arise on the denuded surface of the bone unite or inosculate with the granulations produced from the neighbouring soft parts, and a common cicatrix covers the whole. It is not uncommon to see this process in exposed portions of the cranium, and I have seen instances in which a very considerable portion of the surface of the cranium, and that in elderly persons, has thus produced granulations, and become covered by the production of new flesh, so that a wound, accompanied with extensive exposure of bone, has thus become consolidated without any of what is technically called *exfoliation* of the bone taking place.

I remember an instance of a wound of a contused and lacerated kind in which nearly the whole of the exterior surface of the patella was exposed—it was quite denuded of the periosteal covering. It assumed a brownish appearance, from which I supposed that the surface of the patella would separate. This, however, did not take place; the soft parts united, granulations sprung from the surface of the patella, and no separation took place. I have seen an extensive exposure of the tibia in a compound fracture of the leg, in which I supposed that exfoliation must necessarily ensue, but in which the surrounding soft parts advanced over the bone, granulations sprang up on the bone itself, and thus the wound was healed by the granulating process—partly of the soft textures, and partly of the exposed surface of the bone.

Occasionally, however, the surface of the bone when thus denuded becomes perfectly dead; it then turns of a dull white, and afterwards assumes a brownish or even black colour: when it thus loses its vitality, no pink appearance remains, and we never see any production of those pink spots or irregular prominences. Under such circumstances the portion of the bone exposed dies, and it is to be separated from the healthy bone by a process which is essentially similar to that which takes place in the separation of a slough from the soft parts. Now this, in the case of bone, is called *exfoliation*: it is the process by which the projecting portion of bone, in cases of amputation, is detached from the living bone, and by which a portion of bone which has been denuded is separated, or by which a portion of bone in other parts of the body, when it actually

perishes, is detached from the living part. *Exfoliation* means the separation of a leaf, and in fact the portion of bone which is detached in these cases, is often a thin plate. Hence the name of exfoliation has been given to it.

We find in these cases, as in cases of the mortification of soft parts, that a groove is formed between the dead and the living parts—it seems as if a portion of the substance were eaten away. From the groove which is thus formed, granulations spring up, and these granulations form one mass with the surrounding soft parts, so that the portion of denuded bone is thus surrounded by a sort of ridge of these granulations. The absorbents gradually eat into the bone, deepening the groove which I have just mentioned, extending it under the dead part of the bone, and, in fact, continuing their process until the dead portion is completely undermined and separated from the living. When this process is complete, the exposed part of the bone is found loose when you touch it, or it becomes loose by the application of a very little force. You easily detach it; and when this dead part comes away you do not find that the surface beneath is rough and hard, like that of bone; on the contrary, when the dead part is separated there remains behind a bed of granulations which have gradually passed from the original groove under the dead part, and completed the separation. There is a mass of soft vascular substance remaining, and the part of the bone which is separated bears evident marks in its appearance of the action of the absorbent vessels which belong to these granulations. If you look at any piece of bone thus detached, you see that it presents a number of irregular rough prominences and depressions, which correspond to the prominences and intervals between the granulations.

[Mr. Lawrence here exhibited some specimens in illustration.]

This process, then, of the separation of the dead or exfoliated parts from the living portion, is effected by *absorption*. The bony substance is taken up by the absorbents of the granulations, and thus there is an actual vacancy made between the dead and the living parts. Now it has been stated that this process of absorption must be preceded by some softening of the bone that is to be removed. It has been represented, that we cannot suppose that the absorbents are capable of taking up the solid substance of the bone, and of removing it, but that there must necessarily be some solvent juice secreted, by which the part that is to be removed is previously reduced to a soft state, so as to fit it for the action of the absorbent vessels. If we look at the surface of a portion of bone thus removed, we cannot see a vestige of such solvent action. We see

sharp points and ridges, which shew that it must necessarily have been removed without any thing like solution taking place. There can, in my opinion, be no doubt that the process is simply that of absorption; and, for my own part, I can see no more difficulty in supposing that absorbents should remove bone than in acknowledging what we all know to be the case, that arteries deposit bone.

[Mr. Lawrence here exhibited some specimens, to shew the nature of the process when a portion of bone perishes, and pointed out the soft granulations extending between the dead and the living parts of the bone.]

That is the nature of the process (continued Mr. Lawrence) wherever it occurs; whether it takes place in a part of the long bone, such as the femur, when divided in amputation, or in part of a broad bone, such as those of the cranium.

You will observe, from what I have now stated to you, that the separation of the periosteum from a portion of the bone does not necessarily involve the death of that portion. It is true that the principal supply of blood-vessels proceeds from the periosteum; so that if you have the membrane extensively detached, that portion of the bone will die. But the periosteum is not the sole source of the supply of blood to the bones. There are openings which extend into the interior, through which we see that arteries, for the nourishment of the bone, enter, which ramify in the medullary cavity, and there inosculate with small branches that proceed from the periosteum. Thus the partial separation of the periosteum does not involve the death of the bone from which it is separated, because blood may be conveyed through these nutrient branches.

The *treatment*, then, of a wound in which the bone is exposed, ought not to be conducted on the supposition that this must necessarily separate or exfoliate—yet this is the principle which, in many instances, has guided the treatment of such wounds. You have been directed to insert various extraneous substances, in order to keep them open, to favour the separation of the bone. What are called *tents*—*i. e.* pieces of lint, sponge, plugs of various kinds, have been introduced, to prevent the edges of the wound from approximating, and to allow of the separation of the bone, which it has been supposed must necessarily exfoliate. Nay, when a bone has been wounded, various powerful substances, acids, caustics, and so forth, have been applied to the bone, with a view to promote the separation. All these proceedings were upon an erroneous principle; if the bone is to exfoliate, and must be separated, it will find its way out without our taking the trouble to keep the wound open for that purpose. If

the bone has actually perished, you cannot hasten its separation from the living part by any application of acid or other strong substances to the dead bone. The only judicious course you can pursue in such a wound, is to unite the soft parts over the bone, and do all in your power to promote their adhesion. In a great number of instances you find that a wound will unite readily, and that no separation whatever of bone will take place. But if this does not occur, the bone, when detached, will find its way out without your assistance.

Fractures.

Although the bones are not liable to those kinds of injuries which are so common to the soft parts—that is, to incised, punctured, and other such wounds—they are frequently subject to a species of injury peculiar to themselves—that is, they are liable, under the application of external force, like any other hard substances, to be broken. They give way under the application of certain external violences, and this kind of injury is called *fracture of a bone*; which, I apprehend, you will understand just as well under that simple term as if I were to give the scientific definition of fracture, which I believe is—*solution of continuity in a bone*.

Now the bones, like other organized parts, possess in themselves the power of repairing this kind of injury; the only difference in the process which takes place in the case of such injuries affecting the bone being that it is slower in its course. I have already had occasion to shew you that when the soft parts are divided they become reunited either by adhesion, which is called union by the first intention, or by the process of granulation and cicatrization, which is called union by the second intention. Now the union of the bones is not at all like that of the soft parts occurring by adhesion. We cannot assimilate the two occurrences. The union of a broken bone is more like that of the soft parts, by granulation and cicatrization—though not exactly like that. We observe, that when the broken ends of the bone are brought in contact, and maintained in apposition, that they slowly grow together—that is, that the bone becomes united at the part that has been broken. It has been said sometimes that this arises in consequence of effusion of blood into the interval of the broken ends of the bone, and the subsequent organization of the blood thus effused. This is an explanation that cannot be admitted, because the bone will unite even when there is no blood at all effused; and if blood be effused, as probably in most cases it is, it is absorbed before the union commences. In the progress of the union of a broken bone, we find that considerable swelling occurs in the situation of the fracture—and a swelling

which is rather firm to the feel. This is technically called *callus*. The word *callus* signifies originally merely a lump, and therefore the term simply denotes the circumstance of the swelling that occurs about a fracture. After the fracture has united, there is generally more or less of swelling and irregularity remaining in its neighbourhood; and that also is distinguished by the term *callus*. Hence this has become a kind of technical word to denote the effusion of substance by which the fracture of a bone is consolidated.

Heretofore it was supposed that the broken ends of bones became united together by the effusion into their interstices of a kind of viscid fluid, which gradually hardened, and became converted into the nature of bone. It was even supposed that particular articles of food, or particular articles of medicine, favoured this process. Some earthy matters were heretofore given, under the idea of promoting or assisting in the process of consolidation. Hence the term of *osteacolla* applied to a substance of that kind. When experiments came to be made on living animals, in order to investigate this process, it was soon found that the notion of the effusion of a fluid which gradually hardened and became consolidated, could not be maintained. Duhamel, who undertook to investigate the subject, supposed that it took place from certain changes which occurred in the periosteum. Others conceived that granulations were produced from the broken ends of the bone, and union thus effected. It seems to have been the opinion of Mr. Hunter that the union was effected in the way that I have already mentioned—by the effusion and coagulation of blood in the interval of the broken bone, and by its subsequent organization, corresponding to the views he entertained of the process of adhesion in the soft parts. More accurate investigation, however, has shewn that the process is not effected in any of these ways; and recently the attention of some of the French surgeons and physiologists has been directed to this point, and possibly the account they have given of the mode of union in fractured bones, is the most correct. Dupuytren has particularly investigated this subject, and he has described that when the two ends of a broken long bone are brought together, and maintained in apposition, they become in the first instance united by a swelling, and subsequent ossification of the soft parts immediately surrounding the broken ends of the bone. This forms a kind of case round the fracture, by which the broken ends of the bone are held together for a time; then the broken ends grow together, and become consolidated, so that the bone unites. Thus he makes a distinction between the first or provisional union, which is produced by the swelling and ossification of the surrounding soft parts,

and the ultimate or definitive union which is produced by the agglutination of the two broken ends themselves—calling the former *cal provisional*—the provisional callus; and the latter *cal definit*—the definitive callus.

According to the account he has given, it appears, in the first instance, that is, taking the period from the occurrence of the fracture to the end of about ten days, the periosteum, the cellular substance, the muscles, and the other soft parts immediately surrounding the broken bone, become swelled, and form a considerable tumor, which you can feel externally. All these parts enter into the composition of the swelling; the thickest part of the swelling is opposite to the situation of the fracture, and it is gradually lost in the natural surfaces of the bone in both directions. In the commencement, the tumor is somewhat reddish—that is, there is a determination of blood to it; but towards the latter part of the period I have mentioned—that is, towards the tenth day—this redness or discolouration is lost, and the swelling, when examined internally, has a whitish appearance. In the early part of this period you have, in fact, a mixture of coagulum and fluid blood. Blood is effused from the vessels that are broken in the fracture, and subsequently coagulates. Such is the state of the parts between the commencement and the end of the tenth day; and in this stage there is either a kind of viscid fluid between the ends of the broken bone, or something like a reddish granular substance produced from the extremities of the bone, forming a kind of spongy union between them—nothing at all osseous. In the second period, which extends from the tenth to the twentieth or twenty-first day after the fracture, the swelling that I have just mentioned becomes less in size—it becomes more limited to the immediate neighbourhood of the broken ends of the bone, but it is considerably firmer in its structure;—it begins to assume a fibrous, or a cartilaginous, or something of an osseous structure. During this second period, the fracture admits of motion—that is, the broken ends can be moved on each other; but no grating is produced by such motion—there is no crepitus. The third period extends from the twentieth or twenty-first, to the fortieth, fiftieth, or sixtieth day; and during this time the external swelling which I have just mentioned becomes ossified, and assumes a pretty firm state; the internal swelling of the medullary membrane becomes ossified in a similar manner, and in fact this ossification of the external and internal becomes firm enough to allow the patient to employ the broken bone. In the case of the thigh or the leg, the patient can now support the weight of his body on the bone; but yet, at the same time, the actual extremities of the fracture are not united—

they still remain connected together by the viscid fluid, or the red spongy substance that I have just mentioned, although the fracture at this time is sufficiently consolidated to enable the patient to use the limb—at all events with care. Yet the union is soft enough to allow of the fracture giving way in consequence of any external force or influence, or in consequence of too much weight being rested upon the limb. The fourth period extends from the fortieth, fiftieth, or sixtieth day, to the end of five or six months; and in that time the external swelling becomes completely and firmly ossified, and when you examine it externally, it seems as if the periosteum extended over the swelling to the sound part of the bone. It is firm and strong, and the medullary membrane is firmly ossified; at the same time the extremities of the bone, which hitherto have not been united, are found to be connected, so that you only see the separation, or rather, the situation in which they had been previously separated—as a faint line, when the fractured part is divided longitudinally with a saw. During the fifth period, extending from the fifth or sixth month to the end of about a year, this external provisional callus is entirely absorbed, and the union of the bone becomes so firm, that subsequently the bone will perhaps break more easily in any other situation than in that of the fracture. The provisional callus having served the purpose of keeping the ends of the bone together for a certain time, is entirely removed, and we see nothing more of it; while that part of the provisional callus which is produced by the medullary effusion is also absorbed, and the medullary membrane returns to its natural state.—[Mr. Lawrence illustrated this by exhibiting a long bone (the humerus) which had been fractured; where the ends had been kept in precise apposition, the structure of the bone was completely established.]

Some time ago I had a patient in this hospital, an elderly man, nearly 60 years of age, who had a compound fracture of the tibia, and he died very suddenly in the fourth month from the time of his admission. The fracture had proceeded favourably, and had united very well, so that he had been well enough to get up and walk about the ward. The limb was quite firm, and we considered the bone to be united;—he could use the limb freely. He died suddenly as I have said, and I had an opportunity of ascertaining the state of the tibia. When I laid this bare, it appeared sound externally; but when I had sawn out a part of the tibia (the back part), I was quite surprised to find that the ends of the bone moved freely, although I knew that the patient had walked before his death. I found the state of the bone exactly corresponding to the description I have now given you—namely, that

the fractured ends of the bone were literally not at all united, although four months had elapsed from the time that he met with the accident. They were connected by a soft reddish substance, but I could easily move them upon each other. But these bones were enveloped by a kind of external investment—a sort of ferrule (if I may use the expression) of osseous substance held them together.

Now you are aware that it sometimes happens that the ends of the broken bone are, in fact, not exactly connected with each other—they do not exactly join as they ought to do—yet the bone may be united. Under these circumstances, what Dupuytren has called *cal défini*—the definitive callus—never takes place at all; the broken ends are only in contact by their sides, perhaps. We then find that the bones are united by what he calls the *cal provisionnel*, or provisional callus, which is permanent; and in this way a very firm union may take place.

[Mr. Lawrence here exhibited a specimen, and observed that the bones were riding or overlapping each other, and that the medullary cavity was not found to exist in such a case.]

The resources of nature are very extensive: in such a case, even where the ends of the bones do not come together, they become consolidated, so that the patient can use them. Here is a case [presenting the specimen] where the portions of the bone do not correspond to each other, but have become fixed in a lateral situation. I have seen instances where there has been an interval between the broken ends, and a cross bar has been thrown out between the two, so as to form a union (of the tibia, for instance) sufficient to support the body, although there was no direct union of the upper and lower bone.

It has been known that part of a bone has been broken off in its whole thickness, as in the case of a long bone, the fracture extending into the medullary cavity; it has been broken off, and actually turned round, so that the exterior part of the bone has been towards the medullary cavity, and it has united in that way. There is a specimen of that kind in the Hunterian Museum, where a piece has been detached and turned round, so that a part of the proper exterior surface of the bone has united towards the medullary cavity. This shews you that the bones have very extensive powers of repairing the injuries which they receive, and therefore you are not hastily to conclude, that because an extensive injury has been inflicted it will be necessary to remove the limb, on the supposition that nature is not sufficient to repair injuries, though they be really very considerable.

From this general view of the process by which a fracture is united, you will easily

deduce the practical rules that are to be observed in the management of such accidents. You must bring the broken ends of the bone together, and approximate them, bringing them as nearly as possible into their natural position, retaining them in that position, and keeping the limb quiet, that there may be no danger of their becoming separated. These are the general purposes that are to be followed in the treatment of fractures; but the circumstances of fractures are so various, that it is not sufficient for me to mention to you these general indications; it is necessary to enter somewhat more into detail.

Fractures differ, in the first place, in consequence of the description of bone which they implicate. You may have a fracture in a long, a broad, or a short bone. Now the observations that I have to make respecting the surgical treatment of fractures, apply almost entirely to those of the long bones. The short bones, such as those of the carpus or tarsus, are seldom the subjects of fracture; sometimes, indeed, the os calcis has been fractured, but it is a rare accident. The broad bones are more frequently fractured, yet the fractures of these admit of very little help from surgery, and they generally are much more important, in consequence of the mode in which they affect the parts contained in the cavities formed by such broad bones, than in reference to the fracture itself, as, for instance, in the cranium or pelvis. We cannot do much in these accidents—so far as the mere fracture goes—and thus our observations on fracture refer almost entirely to the long bones.

There is a considerable difference in respect to the nature of the injury and its extent, and the parts which may be involved in different cases. The fracture may affect the middle, compact, or solid part of the bone, or its spongy articular extremities. The direction of the fracture is very various. The bone may be fractured across—*transversely*; it may be broken in a slanting direction—*obliquely*; or it may be broken lengthways—*longitudinally*; but the latter—longitudinal fracture—is uncommon, and hardly takes place except, perhaps, in consequence of gun-shot injuries, where the fracture of a bone is accompanied with fissures or cracks, extending to a considerable distance: under such circumstances, indeed, nearly the whole length of a bone may be split up longitudinally. Partial longitudinal fracture, however, is more common, that is, where a fracture takes place in the lower articular portions either of the femur or the os brachii. The part which constitutes the condyles of both these bones, is occasionally broken longitudinally, the fracture in such cases extending into the joint—which is, of course, rather a serious complication, and with the simple division of the bone you

may have, under certain kinds of violence applied to them, a fissure or crack extending to a considerable distance.

A bone may be broken in one place, or in two places, or a certain part of a bone may be broken into several fragments. Hence the distinction of *single*, *double*, and *comminuted* fractures. You have the injury of bone occurring alone, or it may be accompanied with more or less considerable injury of the surrounding parts; there may be more or less extensive laceration or bruising of the muscles and other soft parts; indeed, there are few fractures in which there are not some of these injuries of the surrounding parts, and in a great number of these accidents such injuries constitute a very important part of the mischief. Fractures are not uncommonly attended with ecchymosis, that is, with laceration of some blood-vessel, and consequent effusion of its contents. This blood may be either diffused in the cellular texture generally, or a considerable quantity may be poured out in one spot:—or lastly, which is a more serious kind of injury, some considerable artery may be wounded, more particularly in the leg, where there are some large arteries lying in contact with the bones.

Fracture is not unfrequently accompanied with the division of the integuments and a protrusion of the broken bone through it,—a wound of the integument communicating with the fracture. This, in English, is called a *compound* fracture. We use the terms simple and compound as opposed to each other;—a simple fracture being a fracture in which there is no external wound connected with the fracture, whether the bone be broken in one or more places;—a compound fracture being one in which there is a wound of the external integuments connected with the broken bone. These terms are not employed exactly in the same way by the French writers. They use the word simple fracture to denote a case where the bone is broken in one place. *Fracture simple* is equivalent to our single fracture; what we call compound fracture they call *fracture compliquée*—complicated fracture, though this term does not answer to what we should understand by the expression, as there may be various other complications with a fracture besides its communicating with the external surface. Then the occurrence of fracture may be complicated with injury of a joint, that is, the fracture may be so seated as to extend into a joint; and there are some rare instances in which fracture has been accompanied with dislocation, though this of course is an uncommon combination, for the violence which produces the injury either causes one of these accidents or the other—seldom both. If it thrust the head of the bone out of the socket, it does not produce fracture, and *vice versa*; therefore, in general, the existence of fracture excludes altogether the idea of luxation, and of course

luxation leads us to suppose that there is no fracture. But there are cases where they are both present together. Some time ago I saw a medical man in whom dislocation of the humerus had occurred, with fracture close to the head of the bone; so that dislocation cannot be relied on as an absolute proof that there is no fracture.

Now, with respect to the *causes* of fracture, we find that bones may be broken by any violence directly or immediately applied; such as a severe blow, or the wheel of a carriage going over a limb, or any other immediate violence of that sort. But more commonly the bones are broken by the indirect application of force—that is, the bones are not broken by the application of violence directly to the point at which the fracture takes place; but a person falls to the ground, and the end of the bone comes to the ground, while the weight of the body rests upon the opposite extremity; and the bone being included between these two forces, gives way at the middle or weakest part—gives way, therefore, in a situation where no external force is applied to it. This is the way that bones are generally broken in consequence of falls.

There are certain causes of fracture which may be considered to be predisposing or remote; circumstances which favour the occurrence of fracture, when bones are placed in such situations as I have just mentioned. In the middle period of life, in which the osseous structure has the greatest degree of strength, such bones, *cæteris paribus*, are least liable to fracture. Fracture takes place more particularly in young and old subjects, where the osseous structure is less firm and possesses less power of resistance. In elderly persons the bones are more brittle than in the active and robust period of life; so that, on the application of considerable violence, fractures take place almost constantly in persons of a certain age. There are certain states of constitution which we cannot perhaps exactly define, which give a disposition to fracture, and bones break without our being able almost to account for the occurrence.

Now I had a patient in Bedlam, an elderly man, who had been there for a great number of years. His arm was broken by a slight cause applied to it; we could hardly tell how it happened; however the bone was united and did very well. Not above two years afterwards, it was found out by accident that his thigh was broken; he had not fallen, nor had any blow been given, and, in fact, after it had occurred, he contrived to walk to his cell. When he got there, he complained of his thigh, and when I examined him I found the thigh broken about the middle. In this instance, as in the preceding, the fracture was treated in the regular way, and it united very well.

There are certain morbid states of the constitution in which fractures take place under the application of a very slight degree of force, such as in healthy individuals would be totally inadequate to produce the effect. It is in this way that bones of cancerous patients have frequently been broken merely from moving in bed, or making some other slight exertion. In these instances we can see pretty well how it is that fracture takes place, for we find the bones of such individuals become considerably softer than natural; a great part of the earthy matter is removed, and perhaps cancerous structure formed in its place.

NERVOUS AFFECTIONS.

To the Editor of the London Medical Gazette.

SIR,

THE observations of Mr. Brodie upon nervous affections, as related in the Gazette for January 30, recalled to my recollection two somewhat curious cases bearing upon this subject; and should they appear to you to possess sufficient interest to communicate to the medical public, they are entirely at your service.

I remain, yours, &c.

R. R. ROBINSON, Surgeon.

Cooper's Row, Trinity-square,
April, 1830.

CASE I.—R. Robey, æt. 45, November 24, 1829: a strong healthy-looking man, states, that he has, from 14 years of age, been subject to epileptic fits, some of greater, and others of less severity; some have subsided of themselves, others have yielded to leeches and blisters, and others have required V. S.; was seized with a fit on 22d, when from the urgency of the spasms he was obliged to be held by several persons. A small ulcer on the lower part of the right leg, which was bruised when in the fit, is very painful; veins of this leg varicose; right inguinal stands enlarged and tender; head-ache, thirst, skin hot, pulse quick, tongue coated, bowels open by salts.

Cal. gr. iij. Ant. Tart. gr. $\frac{1}{2}$. nocte.

Pulv. Rhei 3ss. c. P. Cinn. Co. gr. v. primo mane.

Solut. Mag. Sulph. 3iss. Ant. Tart. gr. $\frac{1}{8}$. sextis horis.

Cataplasm. panis ulceri.

25th, six P.M.—Was seized last night with violent shooting pain, commencing in the right foot, and extending from thence all the way up the leg to the groin, and from thence to the chest; it has continued ever since, more or less, and entirely prevents sleep; he is now in a state of great agony from spasm, which makes him call out and grind his teeth; almost all the muscles of the body in a great degree of tension; is constantly rolling about in bed till he becomes quite exhausted; some thirst, skin hot, pulse sharp, five motions.

Tr. Opii gr. xl. ex. Mist. Camph. 3j. foment. Cham. et cap. Papav.

Nine P.M.—Considerably easier; the least pressure on any part of the right leg immediately brings on the spasm; pain on pressing right hypochondrium; frequent sickness; skin warm, and very moist; pulse 96, wiry.

V.S. ad 3xx. (slight syncope.)
Rep. Tr. Opii.

26th, twelve P.M.—Was easy until last night, at which time he slept for three hours; he then awoke in a violent state of spasm, which has continued at short intervals ever since; no motion; tongue white, moist; pulse regular, soft, 96; skin warm and moist; face flushed; no head-ache; crassamentum cupped, and deeply buffed; right ankle very much swelled and red; the redness also extends some way up the calf. Pressure, not only on the leg, but on the abdomen, brings on the spasm, in which most of the voluntary muscles, those of deglutition excepted, are implicated, and in a great degree of tension,—for a time all sensation is lost, but returns as the spasms and pain relax.

Cal. gr. v. P. Jalapæ 3ss. stat.
Foment. et cataplasm. rep.

Seven P.M.—Continued in great agony until three P.M., but has since been calm and composed, except when he moves his limb, which instantly brings on the spasm; is now calm, breathes freely, muscles flaccid; pulse rather sharp, about 96 or 8; no thirst; skin warm and moist; five motions, dark brown; leg not painful.

Mist. Salinæ 3j. (Liq. Am. Acet. Mist. Camph.)

Tr. Hyoscyam. Liq. Ant. Tart. a. gtt. xv. 6tis horis.

27th.—Spasms at times occur, but are less frequent and severe; leg still inflamed, a puffiness on the outside, two inches above the ankle; no thirst, skin moist, tongue white, bowels open, pulse soft and slow.

Cal. gr. j. o. n. P. Rhei p. m.

Mist. Salin. P. Dov. gr. viij. 6tis horis.

28th.—Slight spasms at times; pressure upon the limb painful, but inflammation is subsiding; no sleep in the night, but has dozed in the day; two motions; pulse soft, 96.

Perstet.

29th.—Some of the same pains and spasms in the right leg, especially when the poultice gets dry, but they do not extend up the body; no sleep; redness subsiding; less pain on pressure; several motions; tongue moist, but particularly white; no fever.

Repetantur Mist. et Catap. Omitt. Cal.

Ol. Ricini ʒiv. p. mane.

30th.—Some slight pain in right leg and left elbow last night; redness subsiding, but great pain upon pressure above the outer malleolus; bowels well open; tongue moist, but still white; night restless.

Perstet.

Dec. 2.—Pain recurred slightly last night, and seems worse every other night.

Quin. Sulph. gr. iij. Opii gr. j. ter die.

4th.—Pain and spasm returned last night nearly as severe as ever, darting up to the head, and pervading the whole body; pressure on any part intolerable. It began about eleven o'clock, and lasted until five A.M. to-day, alternating with hours of ease; a little puffiness over the outer malleolus, which has apparently a fluctuation, but the least pressure is so painful, that it was examined as lightly as possible; bowels well open, no fever, quite easy during the day.

Tr. Hyoscy. ʒj. Liq. Am. Acet. ʒss. ex aqua Hordei ter die.

6th.—Pain returned last night, and lasted from ten P.M. till five A.M. this day, without intermission, during which time he was quite distracted, and the least pressure upon the abdomen, or indeed any part, increased it; more fluctuation to-day in the tumor over the malleolus externus, which was punc-

tured, and a small quantity of pus evacuated; the operation, however, brought on the spasm and pain, which were slightly relieved by strong pressure upon the abdominal muscles; he traced the pain from the outer malleolus along the outside of the leg, under the ham, and from thence up the back part of the thigh to the sciatic notch, and from thence to the head and fingers' ends. Bowels well open.

Repetantur Mistura et Cataplasmata.

8th.—Pain subsided about ten minutes after the operation, and he has been quite easy since; slept well; bowels regular; a slight healthy discharge from the wound.

Cerat simplex—Bandage.

12th.—No return of pain; wound healing up gradually; slight pain in the stomach from indigestion.

Pulv. Rhei ʒss. statim.

20th.—Pain and spasms have returned with great violence every night since last report, commencing sometimes at 5 P.M. sometimes at 4, and sometimes at 3 P.M. Inflammation around the wound increased, but is now subsiding, and he is easier to-day than he has been since the first attack; no fever; general health good.

Ol. Ricini ʒiv. Tr. Opii gtts. x. statim.

Ferri. Carb. ʒj. 4a. quaq. hora.

Foment. rep.

30th.—The matter was discharged from the original sore on the 22d; the pain from that time gradually abated, and is now entirely gone. Slight fungous granulations in the wound, to which pressure has been lightly applied.

Jan. 10th, 1830.—The pressure produced pain; he therefore returned to the poultice: is now quite easy; pressure does not produce pain; swelling of ankle fast subsiding; general health remarkably good.

Perstet.

13th.—Some induration remains; wound quite healed; entirely free from pain since last report, and in very good health.

Feb. 1st.—Remains perfectly well.

REMARKS.—This case, though in some respects resembling the *epilepsia occasionalis* of Cullen, "ab irratione manifesta oriens, et ablata irratione

cessans," in others differs from that disease; and perhaps may, with propriety, be regarded as an inflammation of the neurilema of the whole nervous system, as indicated by the fever, the extreme degree of pain pervading the whole of the integuments of the body, increased on pressure, and the buffed and cupped appearance of the blood withdrawn from the arm, which latter state is allowed to shew itself most frequently in inflammation of the serous membranes, to which class the neurilema properly belongs.

I think also the cause which produced this excitement of the nervous system corroborates this opinion, for its appearance soon after the commencement of the inflammatory state of the ulcer, its intensity being proportioned to the severity of that inflammation, and its sudden cessation when that terminated, leave no doubt in my mind as to the excitement of the nervous system being attributable to the state of the ulcer. Whether the fit had any thing to do with the ulcer or the succeeding symptoms, I will leave others to determine.

The treatment did nothing more than abate the inflammatory action, and to a certain degree mitigate the pain: it did nothing towards arresting the disease in the nervous system. I believe, also, the puncture was rather premature, so that another time, were I to see a similar case, so great was the pain inflicted by the operation in this instance, that I would leave the opening of the abscess to nature.

CASE II.—April 11th, 1826.—J. Tierney, æt. 40, subject to piles, lumbago, and spasms of the abdominal muscles, since 1818; in 1824 he had an attack of paralysis of his right arm, the use of which he recovered in a month; the spasmodic twitchings, however, have increased greatly within the last few days; are not confined to the abdominal muscles, but extend to those of the chest and extremities. The muscles during the paroxysms, which are short but very frequent, are tense; the pain so great that he cannot refrain from calling out. He is constantly writhing in all directions in the bed; his breathing is short; pulse regular, quick, and sharp; tongue clean; skin moist, but hot; motions green.

V. S. ad 3xviij. Opii gr. ij. nocte.
Ol. Ricini ʒj. primo mane.

12th.—Pains and spasms less severe, confined principally to the extremities, especially to the lower. Rested better; crassamentum of the blood drawn not buffy nor cupped, but the serum very yellow. Tongue clean; pulse softer; motions still green; skin warm and perspiring.

16th, six p.m.—Was quite easy till this morning, when, at 9 A.M. he was seized with pain and spasm in almost every muscle, and a state of opisthotonos. Deglutition perfect; slight headache; some bleeding from piles; tongue clean; pulse excited; one green motion.

Pulv. Emet. statim. Vesic. inter scapulas.
Balneum tepidum.

16th, nine p.m.—Spasms less frequent and severe; vomited copiously a dusky green fluid, with particles, like sawdust, floating in it. Pulse 80, regular, softer. Tongue white, and rather dry; slight headache; two dusky brown motions; could not get a bath; has not applied the blister.

Cal. gr. iij. Opii gr. j. nocte.
Ol. Ricini ʒss. p. m. Ves. app.

19th.—Was seized again, at 11 p.m. yesterday, with spasms as before, which continue, and render him exceedingly restless.

Liq. Opii Sed. gttss. xx. statim.
Cal. gr. j. Opii gr. ij. Ext. Colocynth.
gr. v. ter die.

20th.—Was lulled by the opium; went into the bath in the evening, but upon coming out the spasms returned as severely as ever, though not quite so frequently. The muscles principally affected are those of the lower extremities, and those on the sides of the chest; breathing during the paroxysms hurried; tongue dry and white; one motion; pulse regular.

Vesic. perpet. Rep. med.

21st.—Spasms continue very violent; severe pains in the course of the sciatic nerves; piles also very troublesome.

Hirud. xij. ano.
Quin. Sulph. gr. ij. 6tis horis.

23d.—Leeches bled well: he afterwards went into the warm bath. Spasms both less frequent and less severe; bowels much relaxed; erysipelas in right leg and foot; no appetite; tongue brown and dry; pulse regular.

Cataplasma. panis. Pulv. Doveri gr. x. o. n.

25th.—Foot swollen, red, and in parts livid; phlyctenæ near the ankle; leg swollen, puffy, but not red; spasms and pains ceased; delirium; pulse low; bowels relaxed; tongue dry, brown; skin dry.

Catap. stimul. Opii gr. j. 6tis horis.
Cinch. P. 5j. ex vino, frequenter.

28th.—Leg improving at the lower part, but more swollen, and portions of the skin and subjacent cellular tissue sloughing above; sleeps at times; is now sensible. Bowels regular; stools dark; appetite bad; takes chiefly wine and ale.

Opii gr. j. Quin. Sulph. gr. ij. 4tis horis.

May 1st.—Much stronger; inflammation nearly gone; sloughs separated; sinuses have been laid open to-day. Pulse regular; tongue brown, but moister; three motions; sleeps well.

Rep. med.

13th.—Convalescent; sores healed.

REMARKS.—I have seen this man several times since last report; and although he is much freer from the complaint, he at times experiences pain and spasms of the abdominal muscles and lower extremities, always worst in damp weather, and when the piles project and bleed; and, therefore, to the state of the hæmorrhoidal vessels may be ascribed the nervous excitement manifested.

The only things which materially relieved him were the application of leeches to the anus, and the appearance of erysipelatous inflammation of the leg, by which his life was endangered, and which was most probably attributable to the high state of excitement of the nerves of the leg: if so, it not only verifies Mr. Brodie's observation, that the tenderness of these nervous affections may be followed by increased vascularity, a slight degree of swelling and actual inflammation, but shews the possibility of its being followed by very active inflammation, such as will end in suppuration, abscess, ulcer, or mortification.

It is, perhaps, also worthy of note, that in both the cases I have related almost the only muscles not implicated in the spasm were those of deglutition.

I have lately seen another case of spasm, sensation of "knots" and pain in the abdominal muscles, with pain also darting towards the anterior superior spinous process of the ilium, and the

outer part of the thigh; affecting, probably, the nervus cutaneus externus, which was entirely removed by a diarrhœa. This has been stopped by kino and landanum; but the old pain has since returned, though with less severity. This man was formerly subject to piles, which were suddenly checked, but have lately reappeared.

HOUR-GLASS CONTRACTION OF THE UTERUS.

To the Editor of the London Medical Gazette.

SIR,

ON reading over Mr. Moss's case of spasmodic retention of the placenta, in the last number of your valuable Gazette, I am induced to offer a different opinion of the case to that which he has formed, and to explain, for the benefit of junior practitioners, what appears to me to have been the exact state of the uterus, under the circumstances he has described. I speak rather confidently, from having met with, in the course of an extensive practice, many similar cases, though not accompanied with the "traction" of the funis; an occurrence which I am disposed to consider as having had nothing to do in producing that state of the uterus.

Mr. Moss says, "after remaining a couple of hours, and finding no expulsive efforts made by the uterus, I passed my hand into it, as I imagined (my arm being introduced up the vagina to within three inches of the elbow), for the purpose of removing the contents; when I found a firm constriction in its centre, and a portion of the placenta hanging loosely below it."

From about two o'clock on Friday morning until twelve at night, opiates, for the purpose of allaying the spasms, were administered at intervals, and the hand thrice introduced for the purpose of endeavouring to extract the placenta; but all without effect, the spasm continuing as rigid as ever.

Being thus foiled in his attempts to extract the placenta, Mr. Moss was now led to press his hand on the abdomen, and found, to his surprise, from the shape and situation of the uterus, that his fingers had never been within it at

all, but that its mouth was firmly closed by the placenta, and that the uterus had receded so high in the abdomen, thereby elongating the vagina to so great an extent, as led him to suppose he had found his way into the middle of the organ, when in truth he had but arrived at the portal.

Having now discovered what he considered to be the real state of the case, by well-directed efforts he succeeded, with very strong exertions, in relaxing the spasm so as to admit his hand, and immediately withdrew the placenta.

In the course of practice, as I have above stated, I believe I have met with many similar cases to that described by Mr. Moss; indeed I am disposed to think it is one of the most common states of the uterus under which the placenta is found to be retained, when attached to its fundus.

To convey a more exact idea of the state of contraction than I can do by words, I will endeavour, though but a poor draftsman, to trace the form of the uterus with my pen, thus—

- A, fundus uteri contracted over the placenta.
- B, portion of placenta hanging below the contracted fundus.
- C, the cord.
- D, os uteri still obliterated.
- E, vagina.

The contracted fundus, under these circumstances, may always be felt like

a ball just below the umbilicus; and when that is the case, it appears to me needless to observe that the arm could not very well be introduced into the vagina to within three inches of the elbow, without entering the cavity of the uterus.

When this kind of contraction occurs, the stimulus of the hand within the lower part of the uterus will frequently, in a short time, produce a general and regular contraction, and expel the placenta; which effect will be much promoted by making a feint to withdraw the hand, after moving it about for a little; when, if the uterus contract, the lower portion of the placenta may be laid hold of, and it will come away with the hand. Should this favourable effect not be produced by the stimulus of the hand alone, it ought to be gently insinuated, in the form of a cone, into the contracted part, which I have never found fail to bring on a general contraction; but this last mode of proceeding will seldom be required.

I should say that this is not the same state of uterus usually called the hour-glass contraction, but a much more common occurrence. I believe the hour-glass contraction to be rare; yet I am persuaded there are but few practitioners of extensive experience who have not met with such cases.

I trust Mr. Moss will not consider that I mean this as a personal attack upon him, as I give him much merit for manfully bringing the case before the profession.

JAMES HOLBROOK, M.D.

Cheltenham, 6th May, 1830.

To the Editor of the London Medical Gazette.

SIR,

IN your useful journal of last Saturday I read an interesting letter from Mr. Moss, of Eton, on what is commonly called "hour-glass contraction of the uterus." When this state of the organ occurs, it generally follows the expulsion of the fœtus, and I never heard of any one who had met with it previously to that event. In December last, however, I had a very complete case of the latter kind; and it appears to me that

a brief account of its leading features may not be unworthy of publication.

The patient is a healthy woman, 27 years of age, and had been delivered of twins about two years before. On the morning of the 19th, at ten o'clock, having gone the full period of uterogestation, she was attacked with diarrhœa and severe abdominal pains. At six in the morning of the 20th I first saw her. As the above symptoms then continued unabated, and without any signs of labour, I gave her some opium and left her. The diarrhœa and abdominal pains were soon relieved, and shortly after ten o'clock were followed by pains more indicative of uterine action.

At three p.m. I found the os uteri a good deal dilated, and the presentation natural; but the uterine efforts were infrequent, weak, and very irregular. The abdomen was excessively distended, and it was evident, from the outline of the uterus, that its fibres were not acting at all in a regular manner. The patient being much in want of rest, and complaining of acute abdominal pain, I gave her 25 drops of laudanum, and recommended perfect quietude. Soon after five o'clock the pains indicated that the uterus was disposed to act more vigorously; but in a short time its efforts once more became weak and irregular. She, however, obtained a trifling degree of sleep, and the labour appeared slowly to advance.

At five in the morning she complained of severe pain in the abdomen, and on examining its parietes, a striking change had taken place in the figure of the uterus. It now bore a very perfect resemblance to the shape of an hour-glass, being divided into two nearly equal portions, with a narrow neck between them. The upper half, corresponding to the fundus, was completely pyriform; the lower was more of an oblong shape, from the close contraction of its fibres round the fœtus. The hardness and equality of size in both portions of the uterus, led me to conclude that each contained a distinct fœtus. At eight o'clock there was no material change. I left her for three-quarters of an hour, hoping that a more promising state of things would occur about ten o'clock. On my return, I was much pleased to find that the uterine pains had completely superseded the abdominal; that they were increas-

ing in efficacy, and that the labour was now going on as fast as could be expected. A quarter before ten the fœtus was expelled; the uterine tumor gradually subsided, and in a quarter of an hour the placenta was extracted without difficulty or hæmorrhage.

In her former labour, a period of 36 hours elapsed between the birth of the first child and that of the second; and so indisposed was the uterus to act, that it became necessary to rupture the membranes.

An irritable state of the schneiderian membrane has been long acknowledged to indicate a corresponding state of irritation in the intestines; but I am not aware that physiologists have ever considered the above membrane to have any direct sympathy with the uterus, either in health or disease. A case or two has, however, occurred to me, which would seem to warrant the conclusion that such a connexion does sometimes exist in diseases of the uterus.

In the year 1828 I had occasion to replace an inverted uterus. The patient was 51 years of age, and had long been subject to profuse hæmorrhage, severe pain, and distressing sense of weight in the uterine region; whenever these symptoms had recurred, she had been seized with most extraordinary fits of sneezing; this act of sternutation was accompanied with so loud a noise, that the patient could be heard at a very considerable distance. The complete inversion of the organ was at last produced by one of these unusual fits of sneezing. By replacing the inverted part, and making her wear Lawrie's prolapsus bandage, she has been free from any return of the complaint; her health also is restored, and (what is extraordinary) she has never, to this day, had a single fit of violent sneezing.

Had the above affection of the schneiderian membrane been produced by catarrhal inflammation, or intestinal irritation, it would not have been removed by merely placing the uterus "in situ."

Another woman, with a strong constitutional predisposition to hysteria, has for two years been the subject of what Dr. Farre calls "an hysterical condition of the liver." She had, however, become much better, when, in March last, she was alarmed by a report that the chimney of her house was on fire:

she was seized at once with an hysteric paroxysm; this was followed by violent sternutation; in a quarter of an hour the hysteric symptoms recurred, and were in their turn succeeded by the sneezing. This continued, almost without intermission, till two o'clock the following morning; at ten o'clock the same evening, however, I saw her. I found that she had then the globus hystericus, and many other characteristics of hysteria; I found also that she had not been exposed to the usual causes of catarrh; I therefore referred the fits of sternutation to an hysterical origin. I administered a pretty large opiate, and gave her warm water in great quantities: the affection was but little relieved by it. The fits of sneezing were more severe than any I had ever witnessed, and as the head was very painful, the eyes suffused, and the senses rather wandering, I took away 20 ounces of blood from the arm. I then left her, convinced that I had done all that her case would admit of for the present. The sneezing very considerably abated after two o'clock; it continued, however, at intervals, for 36 hours; after that she had great pain in the hepatic region, with copious morbid secretions from that organ and the stomach; these have, however, yielded to the usual remedies, and she may now be said to be in tolerably good health.

I have also seen, once or twice, an irritable state of the impregnated uterus, accompanied by sneezing, itching, pain, and other unpleasant affections of the schneiderian membrane. These cases have convinced me that a sympathy does sometimes exist in disease between the uterus and the mucous membrane of the nostrils; should they lead others to the same conclusion, their publication may not be altogether useless.

I have the honour to be, sir,

Your obedient humble servant,

WILLIAM LOTT.

Bromley, Kent, May 8th, 1830.

TORSION OF ARTERIES.

To the Editor of the London Medical Gazette.

SIR,

HAVING had an opportunity, last winter, of attending the lectures given upon
129.—VI.

surgery by M. Amussat, in the University of Paris, my attention was particularly attracted by that part of them which embraced the subject of torsion or twisting of the extremities of arteries, for the purpose of stopping hæmorrhage; and it having appeared to me that it might be found useful in military practice, I have been induced to throw together the following cursory remarks upon the subject.

M. Amussat observed, that when the extremity of a bleeding artery of an animal is twisted with a pair of forceps to a certain degree, so as to stretch but not to lacerate it, the effusion of blood is arrested, and no recurrence of hæmorrhage takes place.

Upon the discovery of this fact, he proceeded to investigate the causes and means by which he might satisfactorily explain so unexpected a result; and he found that the torsion, although in a different manner, effected nearly the same object as a ligature—namely, the division of the mucous coat of the artery. This similarity of effect seemed the more extraordinary, as the operations differed very materially from each other in their manner of performance, and no such result could, *à priori*, have been expected.

In seeking for an explanation of this circumstance, M. Amussat remarked, that when an artery in a state of extension is cut across, the mucous coat will be found to protrude beyond the extremities of the two other coats, which, together with itself, compose the parietes of the artery, after they have contracted into their ordinary length; from which he drew the following conclusions.

First, that the cellular coat of an artery must possess considerable elasticity. Secondly, the muscular coat, from its being united with the former, accompanies it in its various motions. Thirdly, the mucous coat, from its little connexion with the two others, being united to them only by some slight cellular membrane, does not contract along with them to its ordinary length, but possessing very little elasticity, it continues somewhat extended beyond the divided extremities of the other two. It is also of great importance to observe, that as the mucous coat has very little elastic capability, it of course cannot be extended to such a

degree as either of the others, without being ruptured.

The operation of torsion is performed in the following manner:—The extremity of the bleeding artery is laid hold of with one pair of forceps, which must have a slide upon them, so as to keep them closed when applied to the artery; another pair is to be fixed on the artery about two-eighths of an inch above the former, which is now to be twisted three complete turns, so as to twist the artery in a corresponding degree; while the other forceps holds the artery firm, and confines the effects of the torsion to the space included between them. The operation is thus concluded, and the forceps being withdrawn, a twisted knot remains upon the artery, which, by the above operation, has been forcibly extended, and in consequence, the mucous coat, from its elasticity, has been torn across, and the current of the blood rushing against the detached portion, causes it to be reflected, and to form a sort of plug in the mouth of the artery, which has proved sufficient to resist the impetus of the blood. Indeed, I have seen the radial artery, when twisted on the dead body, bear a very considerable force applied to it by injecting water.

The foregoing are some of the principal remarks relating to the operation, in addition to which it may be observed, that if future experience should confirm its efficiency, and it should be adopted in practice, there are many advantages it will be found to possess over the ligature, which is now the chief resource surgeons depend on for the effectual arrest of hæmorrhage; and more particularly to the military surgeon it must be extremely useful, as it is very much adapted to casualties, which frequently occur in his peculiar practice, from the facility with which it is performed by one operator, its obviating the irritation produced by the ligature acting as a foreign body, and its little liability to accident, from rough or incautious treatment, in the removal of the patient from place to place.

WM. CAMPBELL ROBERTSON,
Hospital Assistant.

ANALYSES & NOTICES OF BOOKS.

“ L'Auteur se tue à allonger ce que le lecteur se tue à abrégé.”—D'ALEMBERT.

Analysis of the works of Dr. S. Smith and Dr. Tweedie on Fever.

[Continued from page 240.]

ART. II.—PATHOLOGY OF FEVER.

THIS chapter commences by some judicious observations on the necessity of “a comparison of the symptoms, as previously observed, with the state of the organs as subsequently ascertained;”—“and by comparing, in all cases, the morbid symptoms with the altered states, we acquire in the end the power of ascertaining, with a high degree of probability, the presence of an event which we cannot see, by the presence of its sign which we can see.”

“The pathology of fever comprehends the morbid changes that take place in the solids and the fluids of the body.” “It is probable that the changes in the fluids are wholly dependent upon those which take place in the solids.” To this last remark we do not subscribe, and we are disappointed in not finding any evidence in support of the probability which Dr. S. advances. Whether the blood is the first part operated on by the poison of fever, or whether the nervous system is first influenced, and the blood affected through the medium of this system, it is of little consequence here to discuss; but certain it is, that the peculiar pathological changes discovered in the solids after death, take place in the course of the disease;—many of them, we believe, but a short time before dissolution, and are more connected with and dependant upon this approaching event than upon the actions going on in the early stages of the fever. There are few things we should receive with more caution than accounts of morbid changes, convinced as we are that but few persons report them accurately. The evidences of dissection are often doubtful even to the experienced morbid anatomist; and we have no authority which directs us clearly what construction to put on certain appearances. Thus, one person seeing a part injected with blood will contend that this alone is evidence of inflammation; as will another, who sees a serous effusion between the mem-

branes of the brain; while in the one case the effusion may be the result of congestion, and in the other the vascularity may be the result of gravitation, or languid capillary circulation, for some short period before dissolution. Mere vascularity is no proof of inflammation. We remember the late Dr. Armstrong being present at an inspection in which he was interested, and the moment he saw the bronchi slit open, and the lining membrane red, he pronounced it to be inflammation. There is nothing more deceptive, nothing more difficult to judge of, than the appearance of the bronchial membrane, a highly vascular and red state of it being produced by many causes foreign to inflammation, as by asphyxia, impeded transmission of blood through the lungs, from disease of the heart, &c.; and therefore the reports of a dissection should be a minutely correct account of the appearances, as vascularity, consolidations, &c.; and not that this organ was inflamed, and that part inflamed, because we have then to depend on the reporter's judgment, which is apt to be defective.

The same order is observed in treating of the pathology, as in the other parts of the work, namely: first, the morbid appearances in the head; next, in the chest; and, lastly, in the abdomen.

Morbid appearances in the Head.—"The arachnoid," says our author, "is seldom or never in a healthy condition, being more vascular, or thickened, or opaque, and milky; and it adheres very often to the dura mater, particularly at the edges of the hemispheres, or along the course of the longitudinal sinus. To the pia mater the arachnoid is also very often adherent at several points! Vascularity of the membranes and brain in different degrees, with some variety as to the firmer or softer condition of the brain." An accumulation of fluid in the ventricles is more common, as reported by our author, than we have been accustomed to meet with: it is still more common to find it in excess between the membranes, often between the dura mater and arachnoid, (which we have never seen almost always between the arachnoid and pia mater. The author speaks also of flakes of lymph and pus beneath the membranes, which may, perhaps, be found where some peculiarity, as a blow, had occurred; but in

fever cases such appearances it has not happened to us to witness. We suspect our author's knowledge of morbid anatomy has been derived almost entirely from the Fever Hospital, or he would not speak of the adhesion of the arachnoid to the dura mater along the course of the longitudinal sinus as the product of a cerebral affection in fever, it being a natural state; but inflammation is always before the Doctor's eyes. Need we remind him, also, that the arachnoid is adherent to the pia mater throughout by a rare cellular tissue, in which run the vessels that go to and from the brain.

Morbid appearances in the Thorax.—The mucous membrane of the bronchi is the most frequently diseased, and its disease, says our author, "is specific and uniform." "It consists of preternatural redness," and its peculiar character is the being uniformly and strikingly darker than in ordinary inflammation, and darker as the bronchi diminish, which "is indicative, not only of increase of vascularity, but of alteration of its structure." Now all these appearances have nothing specific about them. Had Dr. S. been in the habit of examining this membrane under other circumstances he would have found precisely the same condition. When, in addition to vascularity, a muco-purulent secretion is found, then there can be no doubt of inflammation having existed, but without this proof the vascularity goes for nothing: and as to the darker state of the membrane in the smaller bronchi being indicative of increase in its vascularity, and alteration of its structure, we take leave to remark to the Doctor that this is deceptive, the darker colour being the deep colour of the congested lung seen through the more delicate structure of the small bronchi; and as to thickening, it can only arise from a chronic bronchitis. Thickening of this dense and firmly bound down membrane is very rare, indeed of any membrane, the tumefaction, in the case of mucous membranes, being more generally from deposition in the sub-tissue than from thickening of the membrane itself, which its natural structure scarcely admits of.

Morbid appearances in the Abdomen.—These, as our author justly observes, are more particularly met with in the ileum and cæcum, with elevation of the mucous membrane, vascularity, ulceration, and perforation of the intestine;

which have been so very accurately described by many authors as to render a repetition here unnecessary. The author's account of the changes in the membrane is very short; and his remarks on the morbid state of the mucous glands are not quite consistent with their anatomical structure. The spleen is said to be generally soft, and the pancreas frequently hard.

Cases.—We now come to the cases, a formidable phalanx, reaching the number 115. They are generally inappropriate, and form a most extraordinary subject for criticism: we are amazed they should have been allowed to issue from the press in their present imperfect state. They are detailed in the objectionable form of daily reports, and at the same time so imperfectly that it is not possible to draw any conclusion from them. In some the symptoms referring to a particular organ are mentioned to the exclusion of others; of none is there any early history; and to very few is the treatment added, and where it is noticed it refers perhaps only to the blood-letting, an account of the medicines employed being now and then added as a matter of accident apparently. Taken collectively the detail of the cases is very unsatisfactory, affording the reader no means of judging whether some very sudden and unaccountable changes should be attributed to the treatment or to the disease. All cases that enter the hospital appear to be considered as fever by Dr. S. and he has put them down in his book indiscriminately: for instance, we are at a loss to discover the symptoms of the common continued fever in many, the cases being evidently old disease, which was fast conducting its victim to the grave. Thus a vast number of them present all kinds of morbid appearances, which must have modified in a very decided manner those which are peculiar to fever; and our author leaves his reader in the dark as to whether these organic lesions are to be considered as having taken place during the fever, or whether as having existed before; nor can we determine what are his own opinions, though from the tenor of his language he would seem to think that all the organic changes happened during the course of the fever. On this subject we ourselves have no doubt: many of the cases are nothing more nor less than old lesions, or old diseases, still going on, as phthisis, on which fever in some instances has

supervened; and all practical men know that when such happens patients recover with difficulty under skilful treatment, and sink inevitably if active measures are employed. We should like to know the whole treatment of this host of fatal cases, for if the Doctor has attacked them, lancet in hand, there will be no hesitation in accounting for the mortality. We have not leisure to comment on these cases in detail, and, indeed, we should be sorry to undertake the task, for we feel that our patience would forsake us, and we should be led into remarks which we had rather spare our author and ourselves; but we must give a few specimens, in corroboration of the general opinion we have expressed.

We have already spoken of the case of poor Sullivan, than which a more exquisite example cannot be adduced.

The case 9 which is ranked under "cerebral cases," is an instance of death from *intussusception*. The patient was admitted on the eighth day of *fever*; attack commenced with *violent pain in the bowels*, in addition to the common symptoms. *Epigastre still extremely tender; tongue red, clean, moist; no stool for six days; no pain of head or chest; pulse 99*; died on the 10th; and on dissection there was found "eight inches of the jejunum intussuscepted, and the furthest extremity of the intussuscepted part mortified." The membranes and substance of the brain highly vascular; no effusion. What, we would ask, has this case to do with fever? The tongue was moist, and there was no pain of head, no cerebral symptoms; and yet this case is advanced as one of *cerebral affection*, merely because *after death* the brain was found vascular.

Case 25, age 50, admitted on 4th day of disease; has been in a state of intoxication for *several days* past. Died on the 5th. What could this be but intoxication?

Case 46.—On dissection there was discovered tubercles in the lungs, softened, and in a state of suppuration; that is, in a state of phthisis; and, in addition, "the sigmoid flexure of the colon contracted into a small white cord, of very narrow calibre, (a stricture?) the superior extremity of which was blocked up by a large scybula, and beyond it there was a great accumulation of fæces." Here is a case of phthisis, in conjunction with a permanent and complete obstruction of the colon, set down

under *cerebral affections* because there was an injected state of the membranes, with bloody points, and firm brain, and serum in the ventricles. In the history no allusion is made to the chest or abdomen, notwithstanding the disease that existed in both. It is said she lay senseless and delirious when admitted, and died on the sixth day. We are at a loss to discover any relation between this case and the common continued fever. If the Doctor concludes all cases to be cerebral affections in which, after death, there is found effusion under the arachnoid, or in the ventricles, or bloody points, or various consistence of the brain, then we could furnish him with enough to fill a quarto volume; for scarcely is there any instance of lingering death from organic disease of the chest or abdomen, in which one or other of the above appearances will not be found. Will our author be indebted to us for the information, that effusion under the arachnoid is exceedingly common where no affection of the head has existed, depending simply on the peculiarity of the circulation within the cranium, acted upon by mechanical obstruction in the heart or lungs? Will he be indebted to us for informing him, also, that it is common for persons dying with phthisis to be seized a few days before dissolution with heaviness and stupor, ending in delirium, and coma, and effusion into the ventricles? Yet such a case, if admitted into the Fever Hospital, is accounted a case of fever, with cerebral affection.

Case 50 is an example of extensive ossification of the falciform process of the dura mater, with a complete disorganization of the cerebellum: the patient moribund when admitted. What business this case has in a treatise on fever, we know not. The Doctor, surely, has not seen disease any where but in the Fever Hospital, or he would have discovered that in the last days of patients sinking under organic disease, the sensorium is apt to be disturbed, the eye to lose its lustre, and the tongue to grow dry; and are these patients to be considered as dying from fever, and the morbid appearances to be brought forward as illustrative of the effects of fever? If so, then the majority of cases dying in hospitals must be considered as fever: it is inconceivable.

We are unwilling to fatigue our readers by further comments on this strange assemblage of cases, but we must trespass

on their patience to introduce one more. This is No. 8, given as an example of synchus gravior, with thoracic affection. The patient, Potter, was admitted on the fifteenth day of fever; had been affected with severe pain of the head, and giddiness. On admission the pain in the head was nearly gone, but there remained vertigo, indistinctness of mind, with little or no sleep; indeed, all the symptoms referred to the brain, and there was "no indication of pectoral affection." On the 24th day the report states "no change observable until this day; no indication of thoracic affection had hitherto been apparent; but on the morning of the twenty-sixth day of fever dyspnoea came on, with some soreness of the throat, and he expired in the afternoon. On dissection the *cerebral organs* were found *healthy*; the mucous membrane of the bronchi of dark red colour; bronchial glands enlarged; *pleura of right side generally adherent*; *substance of lungs consolidated*; *pericardium contained four ounces of serum*. All these lesions of the chest were beyond doubt old thoracic affections, except the bronchial membrane; and will any pathologist venture to say that such extensive lesion can exist without any indication of pectoral affection? Has the Doctor studied Laennec? This case is adduced as one of thoracic affection, in which there were no signs; and yet, in a former part of the work, he says "the signs of their derangement are never absent, though less obtrusive." This case of Potter, too, is introduced by the following remarks: "but while sufficiently intense (viz. the thoracic affection) to destroy the structure of the organs in which it has its seat, yet it sometimes gives no indication of its presence, or none until the approach of death. In these cases *the cerebral affection is still more intense* than the thoracic; and the manifestation of the symptoms proper to the lung is prevented by the predominance of disease in the brain. Of this the following case affords a striking example." This is the case of Potter, above related, which, according to the author's own statement, is one of intense thoracic affection, with a still more intense cerebral affection. And what does dissection disclose this *still more intense cerebral affection* to be? Why nothing at all: the cerebral organs were found *healthy*. After this, what reliance can be placed on the cerebral indications specified by

our author? We are curious to know the treatment pursued in this case, but it is, as usual, omitted.

The pathology of the fluids, according to Dr. S., is scarcely at all known, and can only be attained by chemical investigation. He therefore has paid no regard to the physical characters of the blood, and makes no allusion to them in any part of his work; at which we are somewhat surprised. But it seems, from an observation in the early part of his treatise, that he was determined to reject all evidence of this kind. "The blood *may* be diseased in fever; but if it be so, these writers do not *know* it, or at least they do not adduce any evidence that they are in possession of such knowledge: they do not appear so much as to have questioned chemistry," p. 32. The writers alluded to, are those who attribute the essence of fever to a morbid condition of the blood. When making this assertion, was Dr. S. ignorant that these writers had advanced evidence of the altered state of the blood, derived from its physical characters?—and if not ignorant of these facts, why assert that they adduce no evidence? It is painful to us to repeat that this is in keeping with the general principle of the book. He acknowledges, with much propriety, that the pathology of the solids in fever has acquired a high degree of perfection;—and how? Not by chemistry, but by an account of the physical changes in these solids. And are not physical changes in the fluids to be regarded? Has it not occurred to Dr. S. in his dissections, to notice "the dissolved state" of the blood; the absence of coagula, and of fibrinous concretions; the thin fluid condition, like muddy claret; the frequent bloody exudations between the membranes of the brain; all shewing peculiar and decided changes? Are not these altered physical properties as manifest as the altered physical properties in the solids? Certainly they are; but prejudice turns away the eye.

From the character of his writings, and the solid basis of his reputation, Soemmering may be looked upon as one of the fathers of science. To the Germans, indeed, he appeared in the light of a contemporary and fellow labourer; but to us, who have only known him in his works, he seems rather to have belonged to another age. We associate his idea with that of Albinus, with whom he possessed so much in common.

Samuel Thomas Von Soemmering was born at Thorn, the 25th of January, 1755. He received the degree of Doctor at the University of Gottingen, in April 1778, and from that period began to establish in Germany that reputation for science which continued to increase with his works. The inaugural dissertation of Soemmering was entitled, *Dissertatio de basi Encephali et Originibus Nervorum Cranio Eegredientium*. Already, in this first and important work, appeared that admirable activity of investigation, and astonishing power of invention, which always characterized the talent of Soemmering. In 1779 he published a volume, in quarto, on the Functions of the Lymphatic System in Health and Disease, and on the application to be made of such knowledge to the purposes of practical medicine.

About this period, so fruitful in moral and political discussions, many philosophers, and among others Raynal and Condorcet, were wont to plead the cause of the negroes, whose emancipation they demanded in vehement and systematic declamations. Attention was directed to this question from every quarter, and it was on this occasion that Soemmering published his Treatise on the Physical Differences which distinguish the Negro from the European. The first edition of this work was published at Mayence, in 1784, and was followed by another, which appeared at Frankfort, in 1785. In the same year our author produced a Dissertation on the small Calculi which are found in the Pineal Gland and its immediate vicinity. Always interested about the brain, Soemmering published a work on the Decussation of the Optic Nerves, and, in 1788, one on the Brain and Spinal Marrow. In the interval between these two publications, he composed a Memoir on Crises and Critical Derangements. Another, in 1788, made much noise in Germany and France, perhaps chiefly owing to the nature of the sub-

BIOGRAPHICAL NOTICE OF SOEMMERING.

THIS distinguished anatomist and physiologist died at Frankfort, March 2d, in the seventy-sixth year of his age.

ject: it was upon the pernicious Effects of Corsets. The numerous discoveries which he had made on the structure of the brain were only known to the Savans, but no sooner did he write about stays than all Europe became familiar with his name!

The cabinet of Cassel contained a magnificent collection of monsters. Soemmering studied with care all the curious examples which were there collated, and, in a treatise on the subject, he described the singular cases which he had remarked in this museum. Even here he contrived to be original, in a description which appeared little calculated for the display of talent. The most able part of these observations is that which relates to acephalous and polycephalous monsters. In 1791 appeared a work on the Cure of Calculus; and in 1795 he composed, in conjunction with T. Wenzel, a very interesting Dissertation on the Bones of Gouty Persons.

It was maintained by some, that fracture of the vertebræ was always mortal: Soemmering combated this opinion; and, in a work which appeared in 1793, he proved, by facts and reasoning thereupon, that even in the cases where chronic disease of the vertebræ has produced their entire destruction, a chance of safety may remain.

We have not yet spoken of one of the works of Soemmering which has obtained the greatest success, and not without cause: it is his *Manual of the Structure of the Human Body*. A great number of editions, published at different times, attest the merit of the work. In some places, indeed, where the art of multiplying editions has become an integral part of literary merit, this would have been no decisive proof; but in Germany, where they do not recompose a book till the former edition has been sold, the repetition of the publication generally shews that the work is meritorious. The one in question is remarkable for the extreme fidelity of the descriptions, as well as for the number and variety of the facts which it contains. Some parts deserve higher commendation; such are the osteology and the description of the brain and nerves. The last, indeed, was always a favourite subject with Soemmering, and among his later works upon it was one entitled, "On the Organ of the Soul." In this he maintains an opinion which has not the merit

of novelty, nor the solidity of his general doctrines; he holds, namely, that the soul has its seat in the humidity which, during life, lubricates the ventricles of the brain. In 1811 he gave an account of some interesting researches regarding the fluid in the nerves, and on its uses and connexion with the nutrition of these organs in the healthy and diseased conditions. Nor must we omit to mention, in relation to this part of the subject, his tables of the base of the brain, in which are represented with great beauty, and we believe with extreme correctness, the principal differences which exist between the encephalon in man and the lower animals.

The Society of Gottingen had published a programme on the causes and prevention of hernia. Soemmering replied to this in a treatise on Umbilical and Inguinal Ruptures. A singular accident attracted public attention to this work: the author had advanced various propositions regarding the effects of high breeches and hot beverages, on the production of hernia. There soon appeared an anonymous criticism on the doctrines advanced by Soemmering, the indecency of which was its most remarkable peculiarity. Several other works on Hernia appeared at different times from the pen and pencil of Soemmering. In the last of these he advanced the opinion now generally adopted, that umbilical hernia never forms in adults through the umbilical cicatrix itself, but in the linea alba in its neighbourhood. The works of Soemmering almost defy enumeration in a notice such as this, but we must add to the list his plates of the Ear, the Eye, and Organs of Voice, and those of the Human Embryo. It is this last which has led the way to the important researches in embryology which have since been carried on by the Germans—Baer, Meckel, Tiedemann, Carus, and others. Soemmering, however, was the first who gave an exact figure of the embryo, and of the successive gradations of its development from the fourth week after conception.

The last work of this illustrious author was on the Fatal Diseases of the Bladder in Old Persons, the first edition of which appeared in 1809, and a second in 1822, being, as we believe, the close of Soemmering's professional writings.

In 1828, Soemmering attained the fiftieth year of his doctorate. It is a

general usage in Germany to celebrate a kind of jubilee in honour of those who have grown old in scientific labours and fame. On this occasion all the most distinguished men in Germany hastened to render homage to the aged philosopher.—*Journal Hebdom.*

ROYAL INSTITUTION,

Friday, May 14, 1830.

WHITLOCK NICHOLL, M.D. VICE-PRESIDENT, IN THE CHAIR.

Lithotrity.

“OBSERVATIONS on Lithotrity, illustrated by experiments; with reference more especially to the improvements introduced by Gruithuisen, Civiale, Le Roy, and Heurteloup.”

MR. GILBERT BURNETT introduced this subject by stating that as, even in France, the country where most had been done, and the chief improvements made, much uncertainty prevailed as to the appropriation of the several stages of discovery which have led to the successive amelioration and almost to the perfection of the lithotritic process, it would be thankless presumption to moot the question here; and hence it should rather be his more grateful task to shew how much modern surgery stands indebted to Gruithuisen, Civiale, Le Roy, and Heurteloup, as colleagues and fellow-labourers in the common cause of humanity, than as rivals contending for that which, as a whole, sheds glory on the illustrious group; but which, if divided, would be imperfect, and add little to the reputation of either.

The elements of lithotrity, like most modern discoveries, may be found scattered through centuries, and some of them belong to very early time; for so long as men have been intolerant of pain, so long must they have attempted to mitigate or remove the tortures of that most dreadful malady, stone in the urinary bladder. The dilatation of the urethra, and the possibility of passing an instrument, *especially a straight one*, through it into the bladder; the seizing and reducing the stone to fragments or to powder, so that it might pass through the enlarged canal; and the injection of fluid into the bladder, by which its sides might be kept away from the in-

strument during the operation, and by which the detritus might be subsequently washed out; these are the three important elements in the process of lithotrity. The ignorance of the ancients of human anatomy, would seem to have led them nearer to one of these points than the comparative proficiency of the moderns; for they, unconscious of the curves of the urethra, used *straight sounds*—a practice which has been generally condemned, and even the possibility of which has, with some few exceptions, been, till very lately, most strenuously denied. The greatly curved sounds and catheters have, however, for many years been lessening their sweeps; and a straight rod, with a quadrant curve at its extreme, is certainly the most efficient for investigating the contents of the bladder. As to the destruction of the stone in the bladder, by means of instruments passed, *not* through the urethra, but through the perineum, so that it might be voided piecemeal, the plan is so ancient that the word *lithotomy*, which, in truth, signifies *cutting the stone*, was thence derived, although it has since been applied to the operation of cutting the bladder for the purpose of extracting the stone entire, which otherwise might have rather been termed cystotomy; and as to the injection of the bladder and the dilatation of the urethra, so that small stones might be extracted or washed through its enlarged canal, the practice has never been lost sight of, and not unfrequently employed. But ancient as these principles of lithotrity undoubtedly are, they were practically of as little use for the removal of urinary calculi as if they had been never known; nor was it till the present day that surgery could boast their efficient union.

Numerous modifications of the apparatus have been already made, and much more numerous, notwithstanding their present very beautiful construction, they still must be. A particular detail of any one apparatus, would therefore be less useful than an enumeration of the parts which are apparently essential to them all. These consist, first, in a straight tube, which may easily be passed through the adult urethra, even when four lines in diameter. Secondly, an elastic forceps contained within this canula, formed, according to circumstances, of two, three, or four elastic branches, which expand to enclose the

stone when pushed beyond the end of the canula through which they act, and which, when partially withdrawn, retain it firmly within their grasp. Thirdly, of a perforator, drill, or excavator, lodged within the forceps, by the action of which upon the stone it is reduced to fragments, or to powder. The various forms of sounds and catheters, and the different kinds of syringes and other subordinate apparatus, although valuable auxiliaries, can scarcely be deemed peculiar essentials of the process.

The most important improvements in the Baron Heurteloup's apparatus, and those chiefly dwelt on by Mr. Burnett, seemed to be the facility with which either or all the branches of the forceps could be moved, together or separately, so that the grasp could be extended from a third to half a circle, and the stone be more securely fixed by withdrawing each branch so that all would act upon it, which otherwise but seldom is the case. The facility with which either perforator, indicator, excavator, &c. can be introduced through the chief forceps, as occasion may require, the use of a smaller forceps to assist in the apprehension of the stone, and more especially in the power of enlarging the crown of the drill, whether virgule or excavator, to any required size, so that a stone which would require many sittings and many holes to be bored through may thus be reduced to a shell at once. Furthermore, the two-branched forceps, or *brisse-coque* (which is an instrument so greatly superior to the *brisse-pierre* of Amusat, that it may be regarded as a new one), both seizes and crushes the fragments, and will destroy with facility flat calculi, which so commonly elude the power of the other instruments.

A very ingenious bed was also shewn; and although it may be considered but subservient to the general plan, when large stones are to be excavated, we cannot but think it a very useful appendage; and such, we feel assured, it will be considered by every surgeon who is anxious not only to destroy the stone, but to destroy it with the greatest possible ease and safety.

The experimental demonstrations, which included not only the mode of using the instruments in the various operations, but also the mechanism by which their actions are produced, were

illustrated by greatly enlarged diagrams of the apparatuses both of Civiale and Heurteloup; and the instruments were all of them taken to pieces, and the parts of which they are constructed separately and conjointly shewn. We congratulate Mr. Burnett upon being the medium of this communication to the profession, and the Baron upon allowing it to be made; for previously, although the instruments and their action had frequently been shewn, there had been a needless mystery preserved about their mechanism, which could not fail, had it been persevered in, to have been highly prejudicial to the philosophic character of the ingenious foreigner by whom they have been designed. The communication also was made but just in time, for a *brisse-coque* has, we are informed, been constructed, which, if not on the same plan as that of the Baron, promises to be at least as effectual; and the separate motions of the several branches of the forceps has been likewise introduced into the instruments of Civiale.

[Diagrams of the bed and of some of the instruments, as well as much interesting information on the subject of Lithotritry, will be found in the communications of Baron Heurteloup in our preceding volume.]

The meeting was extremely well attended—indeed, one of the fullest of the season. In the Library we noticed specimens of selenium and cadmium, some lava (plain and enamelled), such as has been lately used as street labels in Paris, and a memoir "*Sur la Cataracte Congenitale*," presented by Dr. Lusardi. We also examined, with much interest, the very ingenious calculating instruments of M. Palarino.

On Friday next, Mr. Faraday will introduce the subject which was unavoidably postponed a few weeks since—viz. Phonics; with "observations on new musical instruments."

COLLEGE OF PHYSICIANS,

Monday, May 17.

DR. TURNER IN THE CHAIR.

THE first paper, read by Dr. Hawkins, was

On the Acute Inflammation of the Epiglottis, by Dr. Burne.

The author observed, that acute inflammation affecting the epiglottis,

without extending to the contiguous parts, is so rare a disease that but few examples of it are to be found on record. Two cases of this nature, however, have fallen under Dr. Burne's notice, the particulars of which he detailed. The first patient recovered, but the second perished at the end of four days. In both, the most remarkable symptom consisted in the extreme difficulty, or "impossibility," of swallowing, while the throat did not exhibit any appearance of tumefaction.

A journeyman, aged about fifty, at the time he was seen by the author, had been labouring under difficulty of swallowing for thirty hours. So great was the impediment to deglutition, that not a drop of water was allowed to pass. On attempting to look into the throat, the same difficulty was experienced in having the mouth fully opened as is met with in cynanche tonsillaris; but this having, by some perseverance, been overcome, a satisfactory view of the parts was at length obtained. The fauces were "open and unobstructed," having a diffused redness over them. Anxious to determine what might be the cause of the difficult deglutition, the tongue was depressed forcibly, when the epiglottis came into view—prominent, red, swollen, and resembling a Kentish cherry. The complaint was nearly local; consisting in extreme difficulty of swallowing, and in the exhaustion dependent thereon. The system generally sympathised but little,—there was inflammatory fever, indeed, but it was mild. He had been already bled to syncope, leeches had been applied to the throat, and he had been purged. Leeches were again applied and tartar emetic given in pills, while mercurial ointment was rubbed in, to guard against the probable consequence of infiltration about the glottis. This treatment brought the patient up to the fourth day, when the fever and inflammation had subsided, but the epiglottis continued so much swollen as to render the introduction of nourishment in any form extremely difficult, though it now became strongly indicated by the state of exhaustion and by the return of appetite. Next day, however, he was able to swallow fluids, and ultimately did well.

The second case occurred in a lady, far advanced in pregnancy, who was attacked one day with the usual symptoms

of cold and sore throat, to which was added tenderness about the larynx, discoverable by pressure made externally. Next day, deglutition was almost impossible, yet unattended by tumefaction of the fauces. Bleeding was had recourse to, both generally and locally, but the issue was unfavourable. On examination, the epiglottis was found stiff and thickened with traces of pus; the surrounding parts of the larynx were sound; the lungs infiltrated with serous effusion.

The peculiarities, then, in this affection are the extreme difficulty of deglutition, without tumefaction of the fauces, while the respiration remains free. It is distinguished from inflammation of the larynx by the affection of the voice and difficult respiration which attend this last condition. The author of the paper conjectures that epiglottitis, though rare in its simple form, may nevertheless be frequently present in combination with inflammation of the neighbouring parts—especially in scarlatina.

Dr. Baillie remarked how limited the power of bloodletting was in laryngitis; and the same observation holds good as applied to this disease. Dr. Burne thinks that a moderate quantity from the neighbourhood of the inflammation, as from the jugular, followed up by leeches, would probably be the most eligible form of depletion. To this may be added purgatives injected per anum, mercurial inunction, and blisters to the throat. The exhaustion is so considerable from inanition, that it becomes a question whether the stomach-pump might not be used for the introduction of food. Dr. Cholmeley (who, with Mr. Stanley, attended the second case) has also proposed scarification of the epiglottis, as likely to diminish the tumefaction of the part. The symptoms are not such as to require tracheotomy.

The above was followed by

A short Account of the Sandrock Spring, in the Isle of Wight, by Dr. Culvert.

This spring was stated, by Dr. Marcet, to be the strongest chalybeate with which he was acquainted. It contains nearly two grains and a half of sulphate of iron, and two grains of sulphate of alumina, in the ounce; the great strength of which will be more apparent when we add that the water at Tonbridge, which is reckoned a strong chalybeate, does not contain *half a grain of*

iron in the pint. The dose of the Sand-rock spring may be half an ounce three times a-day, diluted with an ounce of plain or of some aromatic water. It has been found useful where other tonic mineral waters are of service, having the advantage of being stronger than any other yet known.

LIGATURE OF THE INTERNAL ILIAC.

WE have lately seen a preparation taken from a patient in whom Dr. Stevens (whose interesting paper on the Blood we analyzed in our No. of May 8th) tied the internal iliac, for an aneurism of the ischiatic artery, which occurred in a black woman at Santa Croix in 1812. The patient lived 10 years, when an opportunity was afforded by her death, from some other disease, of examining the parts, which were afterwards sent to London, and would have remained for an indefinite period in a cellar in the city, had not Dr. Stevens happened to be in town, and to have his attention called to the subject by observing that Mr. Lawrence, in his Lectures (see Gazette, No. 128), alluded only to one case in which the operation had been put in practice. This induced Dr. S. to have his preparation sent to the College of Surgeons, where a minute examination of it was made a few days ago in the presence of Mr. Lawrence, who, we understand, expressed himself as perfectly satisfied. The preparation, though not in good condition, still exhibits the internal iliac converted into an impervious cord where the ligature was applied, and the remains of the aneurismal swelling on the ischiatic artery.

The operation was performed in another case in the West Indies, and we believe that a preparation of the parts, which was sent to Sir A. Cooper, is now in the museum at Guy's. It has also been performed in this country, in America, and at St. Petersburg. In this last case, the Emperor settled a pension on the surgeon who operated.

THE GUACO.

THE guaco, so much extolled as an antidote to the bite of poisonous serpents, (see Gazette, No. 123,) was tried last

week in a case of hydrophobia at St. Thomas's Hospital. It appeared to act as a narcotic, but exerted no decided influence over the disease.

SLANDER AGAINST ONE OF THE SURGEONS OF ST. BARTHOLOMEW'S*.

IN the Magazine of Slander for last week is contained another specimen of the Editor's partiality for dramatic exhibitions. It represents one of the surgeons of St. Bartholomew's refusing to look at a patient in the receiving-room, on the plea of the case being a hopeless one, till he is offered a fee, which so far alters his opinion that he writes a prescription, and pockets the sovereign. This anecdote was sent to us more than three months ago, but we declined publishing it, because we did then, and do still feel convinced, that the circumstances have been misrepresented. It is rather remarkable that we who are accused by the Lancet of being hostile to the surgeon alluded to, should have declined to publish the calumny, while our worthy contemporary not only inserts it, but endeavours to add to its point by a little theatrical embellishment. Is this love of justice or love of slander—or is he ignorant against whom the blow is levelled?

EXTRACTS FROM JOURNALS,

Foreign and Domestic.

POISONING WITH PREPARATIONS OF MERCURY.

M. ORFILA lately read, at the *Academie de Médecine*, a memoir on the above subject, containing some new and important views. The Advocate-General of the *Cour Royale*, at Orleans, demanded of M. Orfila a solution of the following question:—"Does the existence of mercury in its metallic state in the intestinal canal of an individual, prove that he has been poisoned, provided the symptoms of poisoning have been present?" The case was this:—A woman died after having had symptoms of a "bilious" kind. M. Caron, under whose care she was, had not at the time

* See a Note from Mr. Vincent, at page 320, received as this sheet was passing the press.

any suspicion of poison. However, the public functionaries having afterwards been led to suspect foul play, had the body disinterred twenty-five days after the burial. Two perforations were found in the stomach, having this peculiarity, that the serous and muscular tunics were destroyed to a greater extent than the mucous. Globules of quicksilver adhered to the inner surface of the stomach; a still greater number were found in the duodenum, the jejunum contained none, but nearly a drachm of the metal was found in the cæcum, where it presented large globules. Some of these were also observed in the great intestine. The entire quantity of mercury found in different parts of the bowels amounted to about two drachms. But no trace of any poisonous substance was met with. As the woman in whom the mercury was found had not taken any of it, at least so far as was known, during her illness, M. Caron and another medical man stated, that though they could not positively affirm that poison had been administered, still they thought the presumption was that it had.

To solve this problem, Orfila informs us that two sets of experiments were necessary; 1st, to administer to animals mercurial preparations, not mixed with substances capable of decomposing them; and, 2d, to administer them with substances that were calculated to produce that effect. These experiments gave the following results:—

First Series.—Dogs were poisoned with corrosive sublimate: they were buried, and disinterred at the end of from two to four months. No trace of metallic quicksilver was found in the alimentary canal, although the presence of some mercurial preparation was easily determined. The same experiment with the oxides of mercury gave a similar result, except that some globules were found where the black oxide was the one used; but then, it is to be kept in mind, that this preparation naturally contains some portion of metallic quicksilver. Of the mercurial salts, the proto-nitrate is the only one which, after having remained some time in the stomach, is decomposed, so as to afford metallic mercury. This reproduction of the quicksilver is doubtless owing to the presence of a certain quantity of albumen and gelatine in the stomach. Mercurial ointment introduced

into the stomach affords metallic globules at the end of some hours.

Second Series.—If mercurial compounds be administered with substances capable of decomposing them, such as the proto-sulphate of iron, the oil of turpentine, copper, arsenic, zinc, albumen, or gelatine, then metallic quicksilver will not fail to be discovered in the alimentary canal. From this it appears, that if, in an individual who has had symptoms of poisoning, a certain quantity of metallic mercury is found, particularly if along with it there be any substance capable of having effected its decomposition, it is very probable that such individual had been poisoned, provided, however, that it be proved that mercury, in its crude state, had not been introduced into the stomach.

M. Orfila concludes, with regard to the particular case which led to these inquiries, that it is impossible to affirm that poisoning had taken place, although there be room to suspect it.—*Journal Hebdomadaire.*

PRECAUTIONS IN THE OPERATION FOR CATARACT.

A considerable number of cases of cataract have been operated upon during the present season by M. Dupuytren, at the Hôtel Dieu. Depression is the method almost exclusively adopted by him; and in performing this he has the patient placed in bed, and laid on the back, the head being conveniently supported, and fixed. By these means he thinks that accidents from the movements of the patient are best guarded against, as well as those which may occur in transporting him from the operating chair back to his bed. One of the inconveniences which M. Dupuytren has most frequently met with in operating for cataract, with the patient sitting up in a chair, is syncope, a circumstance which proves extremely embarrassing to the surgeon. Last spring, M. Dupuytren was called by M. Husson to a patient who had been operated on for cataract a long time before, and who felt some inconvenience in one of his eyes. The operation had consisted in extraction, and had only been performed on one eye. The patient had been placed in a chair, and scarcely had the surgeon finished the section of the transparent cornea, when he fainted so profoundly that the operation could not be completed; the lens remained in its place;

the wound healed; and some months after the other eye was operated upon by the same surgeon. The method of extraction was adopted on this occasion also; the patient was again placed on a chair, and syncope came on as before, giving rise to very great difficulty and embarrassment. M. Dupuytren was called to him on account of very violent pain which he experienced in the eye which had been incompletely operated on.

Tendency to vomit, and actual vomiting are, as is well known, very frequent after operations for cataract, particularly in children. One of the best methods of removing this, consists in making them drink a few cups of Seltzer water.—*Ibid.*

LETTER TO DR. BURROWS.

To the Editor of the *London Medical Gazette*.

Reigate, 11th May, 1830.

SIR,

AN association of medical men in Surrey, under the title of "The Surrey Benevolent Medical Society," met yesterday at Epsom, and feeling a wish to do some small justice to a worthy, an able, and an honourable man, agreed to address a letter to Dr. Burrows, of which the following is a copy; and at the same time directed me to request the favour of you to cause its insertion in the next number of the *Medical Gazette*.*

I have the honour to be, sir,

Your most obedient servant,

THOS. MARTIN, Sec.

To Dr. Burrows.

Epsom, 10th May, 1830.

SIR,

THE members of the Surrey Medical Society, in consequence of circumstances which have occurred, and from which you have been most strangely and unjustly misrepresented and traduced in the public newspapers, beg permission to express their sympathy, and the assurance of their most cordial and undiminished regard to you, as individually their friend, the friend of this society, of medical science, and of humanity.

Conscious of your integrity, and of the blameless as well as praiseworthy tenor of your professional conduct on all occasions,

* It was impossible for us to insert it last week, from crowd of matter.—E. G.

you hardly stand in need of this assurance from such humble individuals; but you have been so hardly and unjustly treated by the public press* in particular, that they consider your professional brethren may without impropriety state to you, that they are not forgetful of your former labours in behalf of the general practitioner, of the merits of your admirable writings, and of the friendship which they have collectively and individually experienced at your hands.

Wishing you a long career of happiness, success, and of meritorious exertion in behalf of your suffering fellow-creatures, they remain

Your faithful friends and servants,

JOHN PARROTT,
THOMAS MARTIN,
JOHN N. SHELLEY,
GEO. FLETCHER,
JAMES TUNSTALL,
JOSEPH WARD,
GEORGE BOTTOMLEY,
EDWARD WALLACE,
CHARLES COOPER,
THOMAS B. TOOVEY,
JOHN WINSLOW MAYD,
T. W. MONTAGU,
WM. HART,
W. CHALDECOTT,
THOMAS STEELE,
THOMAS SMITH,
ALFRED HARDWICKE.

HOSPITAL REPORTS.

GUY'S HOSPITAL.

Disease of the Spine—Issues—Setons—Mova—Electricity—Convalescence.

MAY 10.—J. Fowler, aged 19 at the time he was admitted into the hospital, which was on the 22d of April, 1829, under the care of Mr. Key. About eighteen months ago from the present date he was seized with pain in the back, between the scapulæ; and in about two months after he perceived a numbness and stiffness of the lower extremities, and extending over the abdomen. By degrees the lower limbs became quite paralyzed, and eventually he lost all power over the rectum and bladder, the urine and feces passing off involuntarily. He states that he applied to a medical practitioner at Avebury, in Wiltshire, where he resided, who made several issues in the back near the spine, from which he derived some benefit at the time they first began to discharge; but this improvement was only temporary. He remained under this gentleman's treatment for about four months, and not getting any better, his medical attendant advised him to go to London.

* Not by the medical press—with one exception.—E. G.

When admitted at this hospital, he was so far deprived of the use of the lower part of his body as to be unable to sit up in a chair without being fastened to it. On examination he did not complain of pain in any part of the spine, or of tenderness on pressure; but the column at about the third and fourth dorsal vertebra was considerably curved backwards, giving to the part the appearance termed hump-back, which left no doubt but that ulceration and absorption were going on in the intervertebral substances, if not in the bones themselves at this situation.

The treatment consisted in introducing a seton on the right side of the spinal column, opposite to the distortion, keeping the patient in bed upon his back, and exhibiting laxatives. Although the urine and feces came away involuntarily, he was conscious of it at the time, but had no power to prevent the occurrence.

In about a week after the seton was made, he was able to move his legs up and down in the bed, and had recovered in a slight degree the use of the bladder and rectum; this however remained but for a short time, and he soon became as ill as ever.

On the 29th another seton was made on the left side of the spine, opposite to the former.

In the month of August he was attacked with fever, and was attended by Dr. Bright. During the febrile excitement he became the subject of almost incessant vomiting, which continued for several days, and for which he was directed to have mustard cataplasms applied over the stomach, and to take effervescing draughts, with tincture of opium, when at length, by these means, the vomiting became arrested. He gradually recovered from the fever, and in about three weeks became convalescent; but the paralysis continued the same. After remaining for some time without any thing further being done, a skein of thread was passed through the track of the first seton; each of the others, as well as this, remained in the wounds about six weeks. As the skeins were removed, the sores were allowed to heal, and he remained for a considerable time without any farther attempt to relieve him, when the application of moxas was had recourse to between the shoulders. In about two months after the febrile attack he could move his lower extremities slightly; and by continuing the use of the moxas he gradually improved. Having remained in bed about ten months, he found that he had gained considerable strength and motion in the lower limbs, and likewise could retain the urine and feces tolerably well. He was now able to stand and support the weight of his body, with the assistance of a chair, for a few minutes, but could not advance one leg before the other.

About six weeks since he was ordered to

have an electric spark passed every day along the course of the spine, and down the back; and he says from this he finds great benefit, and seems to gain strength faster than he has done at any time before. He can now stand without support, and advance one leg before the other. When he feels an inclination to go to stool, he is obliged to be assisted to the water-closet immediately; he passes his urine less frequently, and in a greater quantity at a time. The curvature is much less than what it was when admitted; in fact, it deviates now but very little from the natural line.

Since January he has used an iron support, which he now continues to wear on his back: this instrument is the one first suggested by Sir Astley Cooper in cases of this description.

On Tuesday, May 11th, a boy, seven years of age, was operated on by Mr. B. Cooper, for stone. Mr. C. used the straight staff and scalpel. Two small calculi were extracted, highly polished on the surface. No unfavourable symptoms followed: the wound is now healed, and the boy well.

ST. THOMAS'S HOSPITAL.

Lithotomy—Reaction without Power—Sloughing of Wound—Recovery.

On Friday, April the 9th, Mr. Green performed two operations for stone in the bladder; one was on a man fifty years of age, and the other on a boy aged fourteen. No unfavourable symptoms followed in the former case, which did exceedingly well. In the case of the boy there was nothing remarkable at the time of the operation; he then appeared in perfect health, and did not express any apprehension. The time employed in the cutting process and extraction, did not, in all, exceed five minutes, and he appeared to be doing well until about an hour after, when he complained of being faint, and was soon after attacked with nausea and vomiting. There was a slight oozing of blood from the wound. An opiate draught was given, but this was soon rejected, and nothing further was done than the application of warm camomile to the abdomen, until 9 o'clock P.M. when he was seen by Mr. Green. His pulse was then very low and feeble; his countenance blanched; the vomiting had become more frequent, and his general appearance indicated a state of depression which was not easily accounted for, as the sanguineous discharge had ceased, and could not have exceeded two ounces altogether. He was ordered to take five grains of carbonate of ammonia, with 25 drops of tincture of opium in camphor mixture, immediately. This was again rejected as soon

as swallowed, and on the stomach becoming more composed, half a grain of crude opium was administered by the dresser, Mr. Warde, which was retained, and he was free from vomiting for upwards of an hour, when, as he was continually craving for something to quench his thirst, some barley-water was given him. After this, the vomiting again returned almost immediately, and he continued retching for some time, while the pulse fell till it could scarcely be felt. Brandy was then administered by tea-spoonfuls, with arrow-root, which was returned again almost as soon as swallowed. Pure brandy was given him, and repeated about every quarter of an hour—a tea-spoonful at a time: this was continued for upwards of two hours, when the stomach appeared quite composed. The brandy was repeated at intervals during the night, and the feet being very cold, bottles of hot water were kept applied to them, and camomile timentations to the abdomen as before.

10th, 10 A.M.—He has not vomited until this morning since the brandy was given undiluted, when, without any assignable cause, it has again recurred, and he now rejects this, as well as every thing else, as soon as taken. He does not complain of pain or tenderness on pressure over the abdomen, or in the epigastric region. Pulse scarcely perceptible; tongue white; no oozing of blood has since taken place from the wound.

1 P.M.—Mr. Green again saw him. The dresser had given the patient an effervescing draught, composed of a scruple of carbonate of ammonia, and half an ounce of lemon-juice, with an ounce of water. This the stomach retained for about two hours, after which the vomiting returned as before. The draught was ordered to be repeated, and a mustard poultice applied over the stomach until redness was produced. Finding that he had been accustomed to take gin, this was directed to be given him instead of brandy.

8 P.M.—We visited him, and found that the vomiting had gradually subsided;—he appeared to be more composed. In addition to the gin, he had taken some port wine, with a small quantity of toasted bread. Pulse scarcely to be felt, but appears somewhat stronger since noon. No bleeding from the wound, but plentiful discharge of urine. Feet slightly warm; countenance pale; there is a peculiar diffused blueness over the chest.

12th, 10 A.M.—Has passed a better night than either of the former since the operation. He has had but one attack of vomiting since last report, and that after taking a cup of tea. He continued to take gin and port wine during Saturday night, at intervals, and until Sunday morning about eleven o'clock; up to which time he had taken three ounces and a half of the former and two of the

latter. Pulse 140, and rather sharp; face flushed and blanched alternately; has frequent sighings; eyes sunken, with a glassy appearance; tongue dry; skin hot; complaints of pain across the lower part of the abdomen, with tenderness on pressure. The pain extends down to the perineum. Plentiful escape of urine by the wound, but none as yet through the natural passage. No evacuation from the bowels.

When visited by Mr. Green, at 1 P.M., his pulse was only 120; and it was found that, in this respect, it varied in a short space of time. There was a good deal of tenderness in the perineum on either side of the wound, with dark patches, appearing like ecchymosis, which Mr. G. stated he could not easily account for. The wound looked pale and unhealthy. Mr. G. observed to the pupils, that this was a case where reaction had taken place without power. He ordered a mustard plaister to the abdomen until redness was produced, an enema of warm gruel to be administered, and a tea-spoonful of castor oil to be taken immediately.

9 P.M.—Pulse continues quick and sharp, at present 144; tongue dry and coated at posterior half, red at tip. The bowels not being evacuated, another enema was administered at six; and being yet unevuated, a dessert-spoonful of castor oil was ordered to be given, and hot poultices to be applied over the abdomen, as the pain still continues.

13th.—10 A.M. Has passed a good night and slept several hours; has had no sickness or vomiting; pulse 138, but still varies in frequency; last night the urine flowed through the urethra for the first time, and the bowels were opened thrice by the castor oil. He took during the night a small quantity of beef tea; there was a great inclination to a return of the vomiting. Countenance this morning much improved, and he expresses himself as feeling much better; has but little tenderness in the abdomen on pressure; warmth natural all over the body. At 1 P.M. when Mr. Green saw him, he said he was not quite so well as in the morning; pulse 132, and feeble; he now feels slight pain on pressure over the inguinal regions; has a good deal of tenderness on pressure also in the perineum; wound still looks pale and unhealthy; he is continually asking to have porter and mutton chop; Mr. Green accordingly ordered them. In the evening, when we saw the patient, he had partaken but of a few morsels of the chop, but very much relished the porter, (half a pint in all,) which did not appear to have disagreed with him; he had likewise taken some beef tea.

14th.—10 A.M. Has slept a good deal to-night, and has lost all pain and tenderness on pressure over the abdomen; pulse quick, with more power; tongue clammy, and mor-

bidly red; skin warm; bowels have acted once. 1 P.M. Since the morning he has taken some boiled eel, some beef tea, and arrow root, and an egg; the pulse has slightly increased in fulness and frequency, and his face is flushed; there is still pain about the wound, with hardness of the adjacent parts. He was ordered to continue the porter and mutton chop: after he had taken these, his pulse again rose, the flush of the face increased, and for some little time a gentle diaphoresis appeared all over the body, and he seemed to be going on remarkably well, when about 5 P.M. there was a sudden alteration; he was seized with faintness, making a sensation in his throat as if he was choking, his extremities became extended and spasmodically fixed, and the eye-balls drawn to one side, and all the muscles of the body seemed in perfect rigidity; some cold water was instantly procured, and poured down his throat, and he recovered in a few moments, and soon after fell into a sound sleep, in which he continued for several hours.

15th.—10 A.M. He expresses himself as feeling comfortable; tongue red and rough, a little furred at the root; complains of thirst; pulse 128, more full than yesterday; has passed a good night; skin warm; less blueness of the chest; the sighings have left him, and the countenance is improved; pressure in perineum causes acute pain; the parts around wound still feel hard, but the dark patches less distinct; bowels not open since last report.

Evening.—Has taken a dose of castor oil, which produced a scybalous stool; has also had for diet a mutton chop and some fish; has taken no porter to-day, but drank some barley water.

17th, one, P. M.—Continues to improve; has had a comfortable night; bowels open once this morning; skin warm; thirsty; pulse quick; tongue more moist; urine passes through wound, and likewise by the urethra; free from pain in the bowels, but is the same as to the perineum.

Ordered, infusion of roses, an ounce and a half; sulphate of quinine, a grain and a half; tr. of hyoscyam. fifteen minims, every six hours.

19th.—The wound now begins to discharge healthy looking pus; pulse 118, less sharp; tongue presents a mottled appearance; less thirst; has had a good night; bowels open; urine passes through wound and urethra.

Porter, half a pint daily.

22d.—The patient now appears quite convalescent from all his symptoms, independent of the wound. Since last report, two sloughs of cellular membrane have come away, and there is less tenderness around the edges.

May 1st.—Having visited the patient from time to time, we found that a third slough had escaped from the wound, which afterwards put on a healthy granulating appearance. A poultice was kept applied to the part. There is now but a very small portion of the original wound which remains unclosed, through which occasionally particles of gravel pass with the urine, and this morning the sister removed a considerable portion which presented itself at the opening; it appeared like a chain, consisting of small grains of calculus, adherent to each other by a thready substance.

In every other respect he is quite well.

NOTE FROM MR. VINCENT.

To the Editor of the London Medical Gazette.

SIR,

A FRIEND having directed my attention to a charge brought against one of the surgeons of St. Bartholomew's hospital of having taken a fee from a patient, which has appeared in a weekly publication of last Saturday, (the *Lancet*), and now knowing, by means of some expositions which took place last autumn, that a regular system has been adopted of vilifying my character in that publication; I deem it incumbent upon me to assert publicly that such imputation does not apply to me; and I request you will allow the insertion of this contradiction in your next number, assuring you that I regard such conduct disgraceful, and deserving the reprobation of all upright men.

I am, Sir,

Your obedient servant,

JOHN P. VINCENT.

Lincoln's Inn Fields,

May 29th.

LITERARY ANNOUNCEMENT.

Mr. William Wallace Currie is preparing for the Press, a *Memoir of the Life, Writings, and Correspondence of James Currie, M.D.F.R.S. of Liverpool, Fellow of the Royal College of Physicians, Edinburgh; of the London Medical Society, &c. &c.* In 2 Vols.

ERRATUM.

We have been requested to correct the following error; it occurred in the copy from whence the article was taken:—In the *Memoir of the late Dr. Lister*, in the Number for May 8th, page 214, line 12 from the bottom, for "January," read "February."

W. WILSON, Printer, 57, Skinner-Street, London.

THE LONDON MEDICAL GAZETTE,

BEING A
WEEKLY JOURNAL

OF
Medicine and the Collateral Sciences.

SATURDAY, MAY 29, 1830.

LECTURES ON SURGERY,

Delivered at St. Bartholomew's Hospital,

BY WILLIAM LAWRENCE, F.R.S.

— *Nov 29.*

LECTURE XLVII.

Simple Fractures—Symptoms—various kinds of Displacement—Treatment—Setting the Bone—Bandages—Splints—Administration of Purgatives—circumstances attending Re-union in children and elderly persons.

I MENTIONED to you, gentlemen, in my last lecture, that the resources of nature in the union of bone are often seen in a very striking way in cases where the consolidation of the fracture does not go on exactly according to the regular course; where, instead of the two ends of the fractured bone being brought in proper apposition, one overlaps the other, so that the two ends “ride,” as it is technically called. Under such circumstances, the union takes place by means of the ossification of the external swelling, which I mentioned to you under the term of provisional or temporary callus, and which here becomes the permanent mode of union.

[Mr. Lawrence presented a specimen, and said it was a remarkable example of this process: for several inches one end rode or overlapped the other.]

I also mentioned that in cases where the ends of the bone do not come near together, the intervening soft substance admits of ossific consolidation, so that the bones become sufficiently strengthened at the part where the fracture takes place for the performance of all the motions and functions which properly belong to that part of the body.

[Mr. Lawrence exhibited a specimen of fracture of the tibia, in which the two extremities were by no means in contact, but in which there was a cross-bar thrown out before and behind, which united them. He shewed two

other specimens, in which portions of the bone were lost in consequence of fracture, but in which, he remarked, the union was sufficiently strong to bear the weight of the patient's body. One of the specimens was of the fibula, in which the union was effected by cross shoots of osseous matter.]

Hence you will observe, that nature does a great deal towards the repairing the effect of the injury in these cases, even in instances which appear unfavourable for the exertion of her powers, and this should encourage us, or rather lead us, to take all possible means for bringing the fractured ends of a bone as nearly as we can in apposition, and maintaining them in that posture, in order to avail ourselves to the full extent of those powers which nature exerts in cases of this kind.

I spoke to you in my last lecture of some varieties in the description of fractures—fracture, where there is not merely fracture of the bone at one point, but where a certain portion of bone is broken into several fragments.—[Mr. Lawrence presented specimens in illustration.]—I mentioned to you the difference of longitudinal, transverse, and oblique fractures, and I observed to you that longitudinal fractures were very rare. Now in this specimen [shewing it] the main fracture has been about the middle of the thigh, but the bone has been splintered, and in fact the fissure extends down longitudinally through the inferior half of the femur, so as to reach into the knee-joint: you see the splinter running down, extending to the joint in a longitudinal direction. This is another case where there is a longitudinal fracture at the upper end of the femur, which has been broken longitudinally for the space of five or six inches, and you see the mode in which the injury has been remedied. This is a longitudinal fracture [another specimen] passing through the condyles into the joint; the main fracture was about the middle of the thigh-bone: in fact, the hardness of the substance which belongs to bones renders them liable in their fractures to several of those

occurrences which take place from violence applied to similar dense substances.

I spoke to you in my last lecture of the Causes of Fracture, and in the observations which I then made, I omitted to mention one cause of fracture by which bones in a certain situation are broken, that is, muscular contraction. At the first view you would suppose when you compared the softness of muscle with the hardness of bone, that the power of contraction in the muscles would not be adequate to produce a separation of the substance of bone; we find, however, that it is capable of producing that effect. Fracture of the patella takes place almost constantly, simply in consequence of the powerful contraction of the muscles which are connected with the bone. The olecranon may be broken by the contraction of the muscles which belong to it, and there are even instances of the long bones of the body being broken in consequence of the powerful action of the muscles inserted into them. I have heard of the femur being broken under considerable muscular exertion in persons making a strong effort, without the direct application of external violence to the bone. It is a rare occurrence, but it occasionally takes place; and it is probable that the contraction of the muscles has a great deal to do with fracture in various instances in which we suppose that it has happened simply in consequence of the application of external force.

I have next to speak to you of the effects which fractures produce, the changes in the state of the limb producing what we call the *symptoms*, or the external circumstances, which enable us to recognize the existence of fracture.

Some of the effects of fracture are immediate, and take place directly after the accident has occurred; others occur more remotely. The first and most immediate effect that is observed from fracture is inability—a general and complete inability in the patient to make use of the limb in which the fracture has taken place. A patient has been walking or running; he falls to the ground, and breaks the thigh bone; he attempts to rise, and feels himself quite unable to do so—he cannot support the weight of his body, or bear at all upon the limb. The patient himself is sensible that the bone is fractured; he says immediately, “I have broken my leg;” and when a patient expresses himself in this way, in consequence of complete inability to use the limb, you may be sure that the leg or thigh is broken—it is seldom that the patient is mistaken under such circumstances. In cases of violent bruise a person can rise, and support himself, but commonly in cases of fracture, he feels the bone give way—he is sensible of its breaking or cracking. This inability to use the limb, of course, is more complete in certain bones than in others,

that is, in fracture of the femur or of the os brachii the inability is more complete than in fracture of one of the bones of the fore arm or leg, because, when one bone only is fractured, the other enables the patient in some measure to use the limb. The observation applies more particularly to instances of fracture occurring in the limb where there is but one bone.

Then, generally, a change of figure is observed in the limb,—it is shortened,—it is bent, or it presents some unnatural configuration externally, and that quite suddenly. This also is more particularly observed in the thigh and upper arm than in other situations, that is, where there is only a single bone; for in the leg and fore arm, you may have one bone broken, and no sensible change in the external shape of the limb.

Then, thirdly, on moving the broken bone, the fractured ends, when rubbed against each other, produce a grating sensation, which is perceptible to the patient, and very sensible to the hand of the surgeon who makes the examination. This sensation is technically called *crepitus*, and when it is felt you become quite certain that the bone must be broken. This is to be regarded as a sure, or pathognomic, sign of fracture;—if you feel the grating in the limb decidedly, there can be no doubt that the bone is broken. It must be observed, however, that a fracture may take place, and the fragments of the bone be in such relative situations to each other, as not to rub or grate when the limb is moved. They may be separated more or less, or some soft part may be included between them, so that the mere circumstance of not being able to feel a crepitus does not prove that a fracture has not taken place, although the existence of crepitus is a satisfactory proof that fracture has occurred. These are the primary or immediate symptoms of fractures.

When a bone is broken, it very commonly happens that the fractured ends become displaced, and this displacement may either take place immediately, as the direct consequence of the application of the injury which produces the fracture, or it may take place at some distance of time after the fracture has occurred. The displacement may be primary, or immediate; or it may be secondary, or remote. If a limb is broken by a carriage-wheel going over it, or a heavy substance falling upon it, the fracture may be accompanied at the same moment by the displacement of one of the ends of the bone. The same injury which breaks the bone may displace one of the fragments; very often, however, the bones are not displaced immediately on the accident occurring, but become displaced afterwards, in consequence of the action of the muscles that are connected to one of the fragments;—muscular action is the principal cause of the displacement

which takes place under such circumstances. It is true that the weight of that part of the limb which is furthest from the trunk of the body, may cause displacement: for instance, supposing the arm to be in a horizontal position, and the humerus to be broken—when that takes place, the weight of the hand and fore arm would occasion that part of the arm to drop, and become displaced. But, in many instances in which a limb is fractured, it is so situated as to undergo no displacement from the weight of the inferior part of the member, and in fact, it is not displaced at the time of the accident, but the muscles connected with the lower part, by contracting, gradually displace it afterwards.

The ends of fractures may be displaced in different ways. In the first place, the displacement may occur in the direction of the axis of the limb, just as I mentioned to you of the humerus, where the lower part drops, so that the limb presents a protuberance in front, and a corresponding cavity behind. Now you will observe, that this is a kind of displacement which cannot occur when one of two bones is broke, as in the fore arm and leg,—indeed, most of the various kinds of displacement are observed in fractures of the limbs containing a single bone.

Then the bone may be displaced in the direction of the length of the limb, producing the effect you here see, [pointing to a specimen,] where one end of the bone overlaps the other, or rides. This is a displacement producing an unnatural projection and thickness at one part, but more particularly a general shortening of the limb. When you trace with your hand the outline of the bone, carrying your fingers from the upper extremity of the bone that is connected with the trunk down to the fracture, you come abruptly to a termination—you feel what appears like a rising of the extremity of the bone, in consequence of the mode in which the inferior fragment has been displaced. This has been called the “rising end of the bone,” from the idea which is communicated on first examining the bone, that there is an unnatural projection at the part where the fracture has taken place. In truth, however, this end does not rise; for this extremity of the bone is in the natural position, but it appears to rise, in consequence of the other extremity being pushed out of the natural situation, and drawn behind it. Thus you find generally that the part called the rising end of the bone is in its natural place, while the portion seated below it is the part that is displaced.

Then the bone may be displaced, in the direction of the circumference of the limb; and this also affects the fragment of the bone which is most remote from the trunk. The portion which is connected with the trunk remains in the natural situation, in consequence of that con-

nexion, but the portion below becomes twisted inwards or outwards. For example: in fractures of the thigh, supposing the limb to be broke in the middle and left to itself, you find the inferior fragment of the bone turned outwards, and the leg and the foot will be everted. The inferior fragment turns in the direction in which it is drawn by the action of the strongest muscles connected with it. The position of the inferior fragment is no longer regulated by the attachment which the upper end of the bone has to the trunk of the body, and therefore it obeys the action of the muscles inserted into it. The question as to the position which the bone will take under such circumstances, is simply this—What is the situation in which the action of the muscles will place it? If the fracture be in the thigh, it will turn the lower fragment, and consequently the foot, outwards, into the *everted* position. That is displacement in the direction of the circumference of the limb.

Then the fractured bone may be displaced *laterally*. Supposing the bone is broken through transversely, you may have the two ends in apposition, or corresponding by one half of the surface, or by the edges, so as to constitute a lateral displacement. These are the various ways in which the bones may be displaced in fracture; more particularly in cases of simple fracture.

I have mentioned to you that these displacements are principally effected by the action of the muscles which are connected to the fragments of the bone farthest from the trunk, the cause of the displacement being thus combined with the effect produced by the weight of the lower part of the limb. It is possible, however, for a broken bone to be displaced in consequence of the contraction of the muscles which are connected with the fragment still attached to the trunk. Supposing the fracture to take place at the upper part of the thigh-bone—you then find that the superior fragment may be drawn upwards by the action of the flexor muscles which come out of the pelvis and are inserted into the trochanter minor. Here [shewing a specimen] you observe that the bone forms a complete elbow, the superior fragment having been drawn upwards by the contraction of the flexor muscles. It is a case of fracture occurring in the upper part of the thigh. The lower end of the bone is not drawn up so as to be placed behind the superior fragment, and the shortening of the limb here is not from the overlapping of the bone, but from the angle or elbow produced by the superior fragment being tilted upwards and forwards by the flexor muscles. In the same way, when a fracture takes place near the upper end of the humerus, the action of the *latissimus dorsi*, and other muscles, may displace the upper fragment, and occasion an unnatural prominence in the situation of the

fracture, somewhat similar to that in the thigh.

We have not much to say respecting the *diagnosis* of fractures—that is, the distinction of fractures from other accidents; for the peculiar signs which denote the existence of fracture are so clear and unequivocal, that there is little fear of confounding it with other kinds of accident. However, when fractures take place in the neighbourhood of a joint, they may be confounded with dislocations. In the instances of some joints there is an obscurity in making the distinction: the circumstances, however, on which the distinction depends, will be better appreciated when I speak of particular dislocations. In general it may be observed, that, in cases of dislocation, there is much greater stiffness and inability to move the limb. I do not mean of the patient to move it, but that great difficulty in moving the limb is experienced by another person in examining it: and in this way it is easily distinguished from fracture. In case of a fracture near a joint, another person can move the limb, with pain to the patient, to be sure, but in a greater degree than if dislocation had occurred.

There is a kind of accident described by surgical writers which it is very difficult to distinguish from fracture; the accident is rare, and when it occurs it is treated in the same way as other fractures: it is the separation of the bone from the epiphysis. At a certain period you are aware that the articular ends of bones are united to the shafts of the bone by cartilage, that is, the bone is not one entire piece; and it is possible, from the effect of external violence, that the head of the bone may separate at this cartilaginous part, that is, at the epiphysis. Probably you will not be able to distinguish from the external appearances between such cases and fractures. I therefore need not say any thing farther respecting the diagnosis. I may, however, remark that this separation of the head of the bone can only take place in young subjects, for after a certain age the cartilaginous substance is consolidated, so that the bone constitutes one entire osseous piece.

The circumstances of fracture are so very various, according to the extent of the injury—the number and importance of the parts involved—the age of the individual—and the circumstances in which he is placed, that the *prognosis*, that is, the opinion we form respecting the issue of the case, must be subject to the same kind of variety. Nothing can be more simple than a fracture in a bone, untended with contusion or laceration of the soft parts, occurring in a healthy individual. We know perfectly well, that under judicious management, and that of a simple kind, such an injury will be completely and effectually remedied—the patient incurring no

risk of any serious impediment to the use of the limb. On the contrary, in cases where a bone is extensively broken and comminuted, and where the soft parts are considerably bruised and lacerated—where there is a complication with such accidents, of injury of the arteries, or of the joints—more especially if those accidents occur in elderly persons—in those of bad or unsound constitution; under circumstances where the patient will not have all the comforts and means that are necessary to his restoration, there is great risk, either of great imperfection and deformity in the limb subsequently, or, in fact, great danger to life, in consequence of the more immediate or ultimate effects of such accidents. Thus you have every variety, according as the fracture is simple and the circumstances otherwise favourable, or the injury such as to involve danger to life at the moment, or the loss of the use of the limb, supposing the accident should not prove fatal.

There are many cases of fracture in which the issue is doubtful, without speaking of a case that is of the worst kind, where we entertain an unfavourable opinion from the very commencement. When fractures take place in the neighbourhood of joints, we do not know exactly whether the fracture extends into the joint; we are equally at a loss as to the consequences in cases of fracture where some considerable vessels may have been wounded. There are many instances in which we are under great doubt at the time of the accident occurring, as to what the event of the case may be—where we find it necessary to speak guardedly to the patient, and to his friends, as to the probable issue of the case. There are several instances in which, although we entertain a confident expectation that the injury may be repaired, and that the use of the limb may be recovered, we find it impossible, perhaps, to prevent altogether the occurrence of some deformity. Even under the most judicious management, in certain cases, the exact apposition of the broken ends of the bone is difficult to be accomplished and maintained, and then some difference in the length and figure of the limb is almost inevitable. Frequently, in consequence of the length of time occupied in the treatment, considerable stiffness ensues; the free play of the muscles that are seated about the broken bone is impeded; the constrained position in which the limb is kept produces stiffness of the articulation, immediately adjoining the fracture; and thus more or less imperfection of the motion of the limb is produced, and lasts for a considerable length of time, in many instances of fracture, even in spite of the greatest care.

It has been stated that fractures do not unite in pregnant women; that these remain ununited until the period of utero-gestation is at an end, and that then they become con-

solidated by ossific union. It is not very common to meet with fractures in pregnant women, so that I cannot, from experience, immediately say how this may be. In many instances, however, fractures in pregnant women have united just as they would in other females, so that I doubt altogether, for my own part, the truth of this statement. I have never seen an instance of fracture in a pregnant woman that remained ununited.

I come next to speak to you respecting the treatment of Simple Fractures. I have already mentioned generally the indications of treatment in fractures which are to remove the broken extremities of the bone from the unnatural position into which they may be thrown, and to bring them into exact apposition, and to retain them by suitable mechanical means in a state of as perfect rest as we can accomplish, these means being combined with appropriate treatment for the occasional symptoms that may attend the case. Now the circumstance of retaining the broken ends in apposition to each other, and of keeping them quiet in that state, requires of course that the patient should remain in one position for a considerable length of time; usually it is found necessary to confine the patient to bed during the period occupied in the consolidation of the fracture. It is requisite, therefore, that the bed to which the patient is thus to be confined should possess certain properties, or qualities, which are calculated to answer the ends that we have in view; at all events, it is very desirable that the patient who is doomed to keep his bed for a number of weeks, should be made as comfortable as possible. So far as the treatment of fracture goes, what we want is, that the limb, more especially if it be the lower limb, should be uniformly and regularly supported. We want a level surface for the limb to rest upon; it should be supported equally in the whole of its length. It is, therefore, by no means advantageous to put a patient with a fractured limb on a feather bed, because the heaviest part of the body—the trunk, sinks, depresses the surface, and thus the limb comes to be situated on an inclined plane, so that the weight of the body tends to produce, or at all events to favour, the displacement of the fractured ends of the bone. A hair mattress, or a bed which, with requisite softness, shall be capable of preserving a tolerably uniform surface, is the most advantageous. The support of the bed underneath should be firm; it will be of no use to have a firm mattress if the bed on which it is supported give way under the weight of the patient. Therefore the sacking which is commonly found in bedsteads is not well calculated for this purpose, because it gives way in the middle. It is preferable to have a solid surface for the support of the mattress, made by placing pieces of board across the bedstead, under the surface on which the

trunk of the body and the fractured limb are to rest. Then, having the patient placed on a bed of this kind, having removed the dress, which of course you should do in such a way as not to inflict any additional violence upon the limb, cutting off whatever cannot be removed without injury, you proceed to place the limb as nearly as you can in the natural position; and in doing this you accomplish what persons call, in common language, “ setting the bone,” the object being to draw the broken ends out of any unnatural position into which they may have been thrown, and to bring them into regular contact. This process, which by the vulgar is called setting the bone, divides itself, in learned language, into three parts—extension, counter extension, and coaptation. If the ends of the bone overlap, the object of extension will be to draw the inferior fragment down till it comes to a level with the superior one. An assistant, therefore, takes the inferior end of the limb, and draws it straight, with a view of disengaging it from the upper portion; but if he were to draw the lower end while no force was applied to the upper extremity, the entire limb might obey the force so applied; and instead of having the lower fragment drawn out you might have the whole of the limb and pelvis also, drawn downwards. In order, then, to do this properly, you must have the superior end fixed, and the power applied to it is called the counter-extension: so that opposite force is applied to the two ends of the bone, and the two forces are called extension and counter-extension. Now there are two modes of applying this force: you may either apply the extending power to the inferior extremity of the broken bone, or you may apply it to the part of the limb situated beyond it. For example—in the case of a broken thigh, you may apply the extending power to the leg or foot; and you may apply the counter-extending power either to the pelvis or that portion of the limb above the seat of injury. The French surgeons say, that it is a matter of importance not to apply the extending forces to the part that has suffered the accident, but to the neighbouring parts. They state that the pressure of extension and counter-extension irritates the muscles seated on the fractured limb, excites spasmodic contraction, and thus adds to the pain and difficulty of replacing the fracture. The object, however, may be accomplished either in the one way or the other.

When the displacement of the fracture is remedied, the bones will perhaps come into proper apposition of themselves, and that is technically called the process of coaptation. Now the truth is, in many instances this process is not required at all, because the ends of the bone are not displaced, and therefore we do not want to replace them.

In cases of fracture of the tibia or of the radius, it often happens that the ends of the bone are not displaced, and the setting of the bone therefore is not necessary. However, patients themselves—those who are ignorant of this subject—imagine that in every case where a fracture has occurred, there must be a “setting” of the bone; and therefore they, as well as their friends, are very anxious to know whether the bone be set or not; and they have an idea that the setting is attended with great pain, and therefore unless the limb be pulled about a good deal, they will not believe that the bone is set. Every one must know that where it is not necessary to apply violence, it ought not to be done; the patients, however, cannot endure the idea of setting the bone, and if they have not received the quantum of pain that they calculated upon, they conceive that they have still to undergo it. It is well, therefore, to set the minds of the patients at rest upon that point, and to assure them that the fracture is replaced, though they may not have had what they consider a reasonable share of suffering on the occasion.

Then when the fracture is replaced as well as it can be accomplished, the next consideration is, how it can be retained in its situation? and there are various means to be adopted for this purpose.

It has been a very common practice in this country, introduced by Mr. Pott, and followed in consequence of his recommendation, to place over the limb, in the situation where the fracture has occurred, a piece of *soap plaster*, or some glutinous substances; and if any thing of that kind is to be applied, the ordinary soap plaster, which is a mild substance, may be used; it produces no inconvenience, no irritation of the skin, and sometimes it is a partial defence against the friction of the bandages.

Then bandages are commonly used in fractures, and other mechanical means are applied, with a view to maintain the fragments in their proper position, and to keep the limb at rest. With respect to bandages, sometimes a circular bandage is applied—a roller carried round and round in the ordinary way. In other instances, bandages are used which are hardly ever employed except in cases of fracture. There is a bandage which is called the *eighteen-tailed bandage*, which consists of a longitudinal slip, with transverse slips sewn to it of different lengths, so that they can be applied with the ends folded over each other, and thus encircle the limb with a certain degree of force; at the same time they admit of being applied and undone without elevating the limb, or giving that degree of motion to the fractured part which is necessary in the application of a circular bandage. The bandage of Scultetus is merely an *eighteen-tailed bandage*, in which the transverse pieces are not sewn to-

gether on the common *perpendicular piece*, but on which they are merely spread, so that you can take away one or more pieces when they become soiled, and replace them, from the transverse pieces being unconnected with each other. Now circular bandages are not generally well adapted to the treatment of fracture: the motion of the limb which is necessary for their application is injurious, as it is apt to be attended with a displacement of the fractured ends of the bone. They are also liable to the objection that I mentioned in speaking of bandages applied to parts which have received serious injury—that is, when the limb is swelled in consequence of an injury, the pressure of the bandage becomes very considerable, so as to add to the irritation of the part, and it thus exposes the patient to the risk of more serious consequences; so that, generally speaking, you are to consider that the application of the circular bandage to a fracture is out of use. The 18-tailed bandage, and the bandage of Scultetus, are preferable; and the pressure which these produce sometimes assists materially in keeping the ends of the bone in proper apposition. It has also been found by many persons that the influence which bandages are capable of exercising upon the muscles of the limb tends to diminish the probability of spasm, or convulsive action—tends, in short, to keep the muscles quiet; in fact it is well known, when persons have warning of the approach of the spasm, if the limb be held with a firm pressure, the spasm will not come on while such pressure is continued; and the support of a bandage—the *eighteen-tailed bandage*, for instance—serves the purpose effectually. It is a part, therefore, of the dressing of fractures which ought to be attended to with great care.

Then with respect to the confinement of the bone, and maintaining it in a quiet state—this is to be accomplished partly by the position in which the limb is placed, and partly by those mechanical supports which are called *splints*. In each particular fracture you are to consider what the powers are by which the displacement of the fracture is likely to be accomplished, and you are to choose such position, as far as choice can be made, in which those powers will act with the least effect.

Now, in fractures of the lower extremities, particularly of the thigh, and also in some of the leg, it has been found that the half-bent position of the knee-joint is advisable, and that this is most easily accomplished when the patient is laid on a bed which admits of his having the trunk in a straight position, while, at the lower part, there is a double inclined plane, for the support of the limb. A bed of this kind, which is found very convenient in fractures of the lower extremities, where the patient cannot be moved without considerable pain and

having the position of the limb disturbed, has been invented by Mr. Earle: it is extremely convenient in many cases. It consists in a simple bed, like a common one, which is divided into two parts in the middle by a hinge, so that the upper part can be raised, to bring the trunk in a half-erect or an erect position. The lower part is also divided by a hinge, and it can be raised till it presents a double inclined plane. At the extremity of the lower half, there is a cross-bar attached for the feet, by which they may be supported. A similar bed has been devised by Mr. Amesbury, a gentleman who has paid great attention to injuries, particularly those of the lower limbs. The mechanical aid afforded by these beds is of material advantage in the treatment of fracture—the position of the limb, with reference to its power in maintaining the fractured ends in proper relation to each other, being made an especial consideration in their construction.

Splints are apparatuses made of substances more or less inflexible, capable of giving a degree of firm support to the limb. They are made either of wood or of japanned iron, or of pasteboard; substances that admit of the requisite degree of firmness, and may be accommodated to the figure of the limb. These are meant to surround the limb either in whole or in part, and, as it were, to encircle the member; they must, at all events, be sufficiently long, not only to embrace the fractured limb, but to extend beyond the joints that are connected to the upper and lower fragments of the bone. If they are to confine mechanically any particular bone, you must not apply the splints merely to the bone itself, but extend them to the two neighbouring joints, because the motion of either of these joints produces displacement in the fractured bone. In case of a fractured leg, the splints must extend beyond the knee in the upper direction, and downwards beyond the ankle-joint. In fact, in the lower extremities it is occasionally found necessary to have contrivances to confine the whole of the lower limb. You cannot keep the thigh in a proper position without embracing in the splints the whole of the limb, from the pelvis down to the heel. Now as those substances called splints cannot be immediately applied to a limb without rubbing and irritating the parts to which they are applied, you must protect the limb by padding—that is, by some soft substance, to take off the pressure; and, in fact, the inequalities in the limb require that something should be introduced to bring the limb as nearly as you can to one regular surface. By thus rendering the surface against which the splint presses quite uniform, you distribute the pressure over the limb generally, and prevent any considerable irritation of any one particular point. For this pur-

pose you have pads, which are made of tow, or carded wool, wrapped up in linen or flannel; or you put bran into bags, filling them about two-thirds, so that it can be pressed out into any shape; and thus you render it thicker in one part than in another, according to circumstances. The French (and it is generally said they are neater in their various dressings of fractures than we are) are in the habit of applying a substance for which we have no word in English; it is called *balle d'avoine*—consisting of the external husk of the oat, a kind of chaff. It is a very light substance, which, like bran, can be moved from one part of the pad to another, so that you can have the pad accommodated as the limb may require. The object, in short, is to have a soft lining to the splints, so that you may render the surface against which the pressure is applied general over the limb, and avoid excoriating the parts. Tow, lint, bran, and various substances of this kind, may be applied in particular instances, according to the exigencies of the case. Then having replaced the fractured ends of the bone in the way that I have mentioned, having covered the fractured part with a soap plaster, having applied an eighteen-tailed bandage, and then put on your splints, and lastly, having placed the patient in a suitable posture, according to the circumstances that I have mentioned to you,—you have done what is necessary for the treatment of a simple fracture.

I have already mentioned to you, that such injuries require a considerable period of time for their consolidation; that the temporary union, the provisional callus which holds the ends of the bone together, is not fully ossified before 40, 50, or 60 days, and that the definitive callus, or ossific consolidation of the broken ends of the bones themselves, does not take place till a much later period. The most perfect mode of treating a fracture would be, if it could be accomplished, when we have replaced the fractured ends of the bone, and have put on the apparatus that I have mentioned, to let the limb remain without any disturbance until it becomes firmly consolidated; in fact, if there is no external wound, if no particular circumstances occur, and if the apparatus is well applied, there is no necessity for undoing it till the consolidation is fully effected. In general, however, we are hardly fortunate enough to accomplish this. The patient experiences pain or uneasiness from some part of the apparatus—we undo it, and endeavour to remedy the inconvenience. We find, perhaps, that the ends of the bones are not exactly in apposition; we replace them,—and we continue these attentions as often as they are required until the consolidation is effected.

The diet of a patient—for the case supposes a person who is confined to his bed, and

using no kind of exercise—of course need not be very nutritious. In the early part of the case, we may reasonably expect more or less swelling and inflammation in the neighbourhood of the fracture; the patient, therefore, should be placed on light diet, he should not take fermented liquors at all, and very little, if any, animal food. But when the first few days have passed by, and the risk of inflammation is removed, he need not be restricted to so low a diet, although mild and light nourishment is the most proper throughout, except under particular circumstances. If any thing like inflammatory disturbance come on, of course reduced diet is requisite, together with other means necessary to check such disturbance. It is advisable to take care that the bowels do not become confined; but it is by no means advantageous, on the contrary, it is very inconvenient, to purge patients. There is much inconvenience in passing the evacuations, from the moving of the body, and the displacement of the bone consequent thereon; we, therefore, should not give aperients that act frequently, or irritate the bowels.

You will probably inquire what is the length of time within which fractures may be expected to be consolidated? Now it has been very generally stated, that this requires 40 days, or about six weeks. The time required, however, as we might suppose, *a priori*, will be different according to circumstances. We may state, perhaps, that the consolidation of a fracture will require from a fortnight to seven or eight weeks; it sometimes takes place in less than a fortnight in children, in whom the process of growth is extremely rapid. Thus fractures are readily united in children; indeed, you are surprised to see how soon the union is effected. In elderly persons you often find even at the end of six or seven weeks that the bones are not united, that they are quite moveable on each other, and are likely to require a much longer time for their consolidation. In general I should observe too with respect to children, we might fear that deformity would ensue from not being able, in many instances, to restrain them. The movements of these young subjects occasion a good deal of apprehension, but it is generally found that the fractures do very well. We cannot, perhaps, keep the splints on as tightly or as well adjusted as we could wish, and after a few days the little patients will be moving about in spite of all we can do to restrain them; but, I believe, they do not begin to move till they feel that they can do so without inconvenience to themselves, and when that is the case, I imagine their movements do not produce much injury to the parts, for we usually observe that fractures turn out very well in children.

OBSERVATIONS

ON THE

ANATOMY, PHYSIOLOGY, AND DISEASES OF THE CRYSTALLINE LENS,

And their Treatment.

BY RICHARD MIDDLEMORE.

Structure of the Lens.

THE crystalline lens is generally described as a double convex transparent body, situated partly within a cavity at the anterior part of the vitreous humour, in which situation it is fixed by the connexion of its capsule with the hyaloid membrane: in the adult state it has the consistence of soft jelly at its surface, gradually increasing in density as we approach its centre, where it possesses considerable firmness: after maceration it separates into equal parts, each of which is found to be lamellar, bearing a close resemblance to the layers of an onion.

Leuvenhoeck first observed the fibrous structure of the lens, and has entered into a very minute calculation respecting the number of layers which form it, and their mode of connexion with each other. Many, and very contrary opinions, were formerly entertained upon this subject, its anatomy being generally modified by some peculiar notions concerning vision. It must not, however, be forgotten, that many excellent anatomists, and amongst others, John Hunter, believed it to be muscular, and on that supposition accounted for the alteration of figure it was presumed to undergo in the inspection of extremely distant or proximate objects.

It has been said that the lens is not nourished by the circulation of blood through its substance; that no vessels for the purpose of circulating the vital fluid exist in it; that, in short, the lens is a secretion like the liquor morgagni, or the aqueous humour. When we refer to the circumstances of its growth and decay, its situation and its diseases, it would seem to be impossible for such an idea to be seriously entertained by any reflecting mind; but it is an undoubted fact, that such an opinion has been extensively prevalent, and is not at the present day by any means deserted. The crystalline lens is, in early life, small and soft; with increasing years it acquires volume and firmness; in ad-

vanced life it becomes, independently of any morbid action, smaller and harder, thus experiencing the same changes as other parts in their approach to maturity, their perfection, and their decay.

We find it floating in a fluid, suspended by minute and delicate threads, whereby its alterations of figure are readily permitted, without any corrugation or stretching of its capsule. We perceive its use, namely, the refraction of light, and naturally inquire why, if nerves need a vascular supply to enable them to convey sensations, is the same support denied to a part whose office it is to transmit and refract light? Again, if we examine its diseases, we may observe it undergoing change of consistence and figure, and other morbid alterations.

Zinn, Haller, Winslow, and many other celebrated anatomists, have seen blood-vessels ramifying through the substance of the lens, and have represented, or described their course and origin. Even Walther, who was anxious to disprove its circulation, professes to have seen, under circumstances of disease, vessels arranged in a beautiful wreath within it. This admission on the part of Walther must weaken our opinion of his accuracy, for it is contrary to all analogy to find a part retaining its life in the living system nourished in two modes at one and the same time; nor is it very reasonable to assume that a part can preserve its vitality by an organization different from that destined for its support. We can readily perceive how vessels may shoot into an effused inorganic mass, as lymph or blood, or into any other similar medium possessing sufficient firmness to support them, but unless we are prepared to believe that blood may become organized whilst flowing through its proper channels, we cannot justifiably allow the establishment of a circulation in a living part destined to receive and maintain its life by absorption; we cannot admit this change in the mode of subsistence of parts. We infer that the function of the lens produces the same exhaustion and loss as the conveyance of sensations occasions to nerves, and have consequently pointed out a necessity for some reparative process. If the lens does not receive blood-vessels through the medium of its enveloping membrane, how is it nourished? I know only of two modes which bear the

semblance of rational conjectures: I allude to absorption and secretion. The primitive secretion of the capsule (the liquor morgagni) has been said to constitute the support of its secondary secretion (the lens). I am not aware that any vessels similar to the absorbing system of vegetables has been found to exist in the lens, nor can I conceive how such a discovery can be made by those individuals (and they only can be desirous to make it) who have asserted that blood-vessels, from the circumstance of their minuteness, cannot be detected; and who, on this ground only, have sought out some other mode by which it could obtain its nutrition; such a position, therefore, is perfectly gratuitous, contrary to facts, opposed to analogy, and at variance with the general laws of nature. If the lens be supposed to be a secretion from the vessels of the capsule, we must admit that its disease ought invariably to precede that of the lens, the latter having no morbid action of its own. This, however, is not the case; we find one or other part diseased, just as alteration in its own circulation, or other causes, affect it. Again, upon this supposition, it must be removed and repaired, either by the transmission of particles through the liquor morgagni, or by the termination of vessels upon its edge. In the former case the effect of gravity would destroy, and in the latter, inequality of deposition and absorption would interfere with its circularity, and, consequently, with its functions. If we cede to the vessels of the capsule a power of propelling the particles through the morgagnian fluid, we acknowledge the existence of a process incompatible with minute and delicate vision; if we admit the termination of vessels upon the edge of the lens, and do not grant them an attachment there, we deny them that power of adjustment which is here indispensably requisite. Zinn, after having remarked that Petit denied the vascularity of the lens, and believed it to exist in a manner similar to that of vegetables, adds, "*sed recentiorum observationes ericeerunt, vascula non solum, ad capsulam deferri, sed per illam ad interiorem lentis substantiam penetrare.*" He also remarks, (but omits to mention that Winslow's discovery took place in the eye of a fœtus,) "*sic ipse Winslowus affirmat, subtilissimas injectiones sibi aliquando sic successisse, ut vascula*

ipsam lentis crystallinæ substantiam penetrantia invenerit;" and joins to this testimony the opinion of Albinus, who discovered the vessels of the lens as they passed through its front and back surface. Haller and Mœhringius saw and demonstrated vessels passing from the ciliary processes, and ramifying through the substance of the lens. The latter anatomist goes on to mention that more subtle and accurate injections have proved the existence of vessels arising from the artery of the retina, which first ramify upon the posterior capsule, plunging afterwards into the body of the lens; and, also, other vessels, which proceed from the inner to the anterior capsule, to be distributed upon its front surface. Senac saw an artery diffused through the lens in the eye of a horse; and the combined evidence of Camper, Senac, Albinus, and many other celebrated anatomists, would appear to render it certain that the front part of the capsule receives vessels from the ciliary processes, and its posterior surface from the central artery, which are thence distributed, with a miraculous minuteness, throughout the texture of the lens. Ruych, in his early experiments, denied the vascularity of the capsule and the cells of the vitreous humour: he says, on one occasion, "I have represented portions of the tunics of the vitreous and crystalline humours by a spot, not being able to exhibit them in any other manner, on account of their extreme delicacy, and their want of blood-vessels." In the succeeding volume of his works, we find, amongst others, figure 8, with this explanation: "*Demonstratur humor crystallinus, vitulinus, cum ejusdem membranula ambiente, aranea dicta, per quam, plurimæ sunt disseminatæ repletæ arteriolæ.*" I am informed that he unequivocally acknowledged the existence of blood-vessels in the substance of the lens itself; but after a careful examination of his works, I cannot discover any distinct avowal of such a belief, although he has, on several occasions, expressed himself so ambiguously that it is almost impossible to decide what his actual opinion was. Sæmmering has given an admirable representation of the abundance and size of the vessels of the capsule, and has thus explained that representation: "*Trunculus arteriæ centralis retinæ, qui per medium humorem vitreum ad capsulam usque lentis porri-*

gitur, ubi ramulos stellatos seu radiatos quaquaversum dimittit, ita tamen, ut multiplici modo crassiores ramuli gracilioribus per vices succedant." Dr. Young and Mr. Hunter believed the lens to be muscular; and as they admitted no other mode by which muscles were nourished except by the circulation of blood, it follows that both those eminent men entertained upon this subject the popular opinion. Beer asserted that many cataracts arose from a slow insidious inflammation of the lens, and more particularly its capsule. That the capsule may inflame, and become opaque in consequence, is, I think, unquestionable; but, compared with the lens, it is a highly-organized part, and will bear a degree of excitement, a duration and severity of inflammation, which, without proceeding to a destructive extent, may terminate in loss of transparency. Mr. Bell believes that when the lens is in a natural state, it does not admit of the circulation of any appreciable quantity of red blood, but that when inflamed, blood-vessels may be easily distinguished. The latter assertion I believe to be incorrect, and shall beg leave to observe, that what Mr. Bell believed to be an inflamed lens was nothing more than an organized mass of lymph, or other adventitious deposition. After the most careful examination of the eyes of a variety of animals, in whom cataract has been occasioned by accident, (and wounds of the lens, would, I presume, be as likely as any thing to excite inflammation), I have seen no such appearance—no evidence of enlargement of vessels; whilst, in the cataract of old persons, such is the density of the lens that augmentation of their size could not possibly take place. Mr. Stanley, after having remarked that the capsule is nourished by a branch of the central artery of the retina, adds, that after a successful injection, a vessel proceeding to the substance of the lens may be observed. When speaking of the causes of cataract, I shall bring forward other evidence in favour of the vascularity of the lens. The office of the lens is, to refract the rays of light in their passage to the retina; but independently of the unvarying accuracy with which it produces this effect, it would appear to have the power of enabling the eye to adapt itself to objects which are either very near to, or distant from it. This effect is not, however,

occasioned merely by the alteration in the figure of the lens—the entire shape of the globe is capable of being changed by the action of its muscles. There is an evident necessity for some power by which the eye may be capable of varying its refractive power; and I know of no part which, by its alteration, is capable of producing this effect efficiently, except the crystalline lens. John Hunter believed the lens to be muscular, and Dr. Young has particularly described not only its muscles, but the tendons in which they terminate. His description (which argues either very great credulity on the part of a most learned and scientific man, or unusual powers of vision) is as follows: “After having premised the absolute necessity of an increased convexity of the lens when inspecting objects very near to the eye, he says, “the crystalline lens of the ox is an orbicular convex transparent body, composed of a considerable number of similar coats, of which the exterior closely adhere to the interior. Each of these coats consists of six muscles, intermixed with a gelatinous substance, and attached to six membranous tendons. Three of the tendons are anterior, three posterior; their length is about two-thirds of the semi-diameter of their coat; their arrangement is that of three equal and equidistant rays, meeting in the axis of the crystalline; one of the anterior is directed towards the outer angle of the eye, and one of the posterior towards the inner angle, so that the posterior are placed opposite to the middle of the interstices of the anterior; and planes passing through each of the six, and through the axis, would mark on either surface six regular and equidistant rays. The muscular fibres arise from both sides of each tendon; they diverge till they reach the greatest circumference of the coat, and, having passed it, they again converge, till they are attached respectively to the sides of the nearest tendon of the opposite surface. The anterior or posterior portion of the six viewed together, exhibit the appearance of three penniform-radiated muscles. The anterior tendons of all the coats are situated in the same planes, and the posterior ones in the continuations of these planes, beyond the axis. Such an arrangement of fibres can be accounted for on no other supposition than that of muscularity. This mass is enclosed in a strong membranous capsule, to which it is loosely

connected by minute vessels and nerves; and the connexion is more observable near its greatest circumference. Between the mass and its capsule is found a considerable quantity of an aqueous fluid, the liquid of the crystalline.” This is perhaps seeing more than is necessary: if a power of altering its figure be the aid of muscularity, elasticity, or any other means, as the stimulus of near or distant objects may require, he ceded, we have all that is requisite for our purpose, for the explanation of a phenomenon which has ever peculiarly distinguished the human eye, as in many respects the perfection of an optical instrument. The lens being situated in a medium which admits of its greater or lesser degree of convexity, without producing collapse of its enveloping membrane; being somewhat dense and laminated, by which its particles allow a certain extent of motion, whilst its firmness enables it to regain its original form, when the stimulus which excited it to action has ceased, and presents a resistance of structure sufficiently great to admit of the action of those powers by which this change is presumed to be accomplished; and being muscular, and possessing some property by which its degree of convexity may be increased or diminished, is enabled by the aid of the alteration on the figure of the globe, occasioned by the action of its muscles readily to adapt itself to the inspection of proximate or distant objects. I have said that the liquor morgagni enables the lens to move with freedom, and fills up the inequalities which would be left in the capsule whenever any alteration in its figure took place; that, when pressed from one part it readily flows into another, and presents that partial stretching and flaccidity which would arise (did not such a provision exist) from the change of form to which the lens is exposed; and this opinion is strengthened by the consideration, that in this part there is a much larger quantity of fluid, in proportion to its size, than in other situations where fluid is secreted merely for the purpose of assisting the free motion of parts upon each other.

Diseases of the Lens.

Cataract is the most important of all the diseases to which the lens is subject, and chiefly so on account of the frequency of its occurrence. By this term is generally understood,

at the present day, an indistinctness of vision, induced by opacity of the capsule or its contents. Beer, who has written admirably upon this subject, divides cataract into the genuine and spurious; under each of which heads he arranges many varieties, which are also subjected to subdivision; any peculiarity of colour or consistence, or any circumstance pointing out a singularity of appearance, being considered by him worthy of a name. This diffusive subdivision has not, in my opinion, any advantages, and cannot be considered a plan worthy of imitation, on account of the needless obscurity and difficulty it adds to the subject, and the little advantage we derive from it in our treatment of this malady.

I shall enumerate, as distinct forms of cataract, the capsular, the lenticular, and the capsulo-lenticular: the anterior, or the posterior capsule, may be separately, either partially or totally opaque, or both may have lost their transparency in a greater or less degree. In addition to this, we may have, combined with a partial or total opacity of the lens, any grade of opacity of either the anterior or posterior capsule, or both. The lens alone may be affected; and it more generally happens that lenticular cataract exists as a separate form of disease, than capsular. I know nothing of the morgagnian cataract as a distinct disease; if capsular cataract exist, the liquor morgagni is, I presume, very likely to become dull and turbid. Cataract has been distinguished by its colour, its consistence, its duration, and a variety of other unimportant circumstances: it has been said to be hard or soft, according as its density has been increased or diminished; green, or marbled, in accordance with a particular change of colour;—mature or immature, as indicating its incipient or fully formed state. Simple uncomplicated cataract may be distinguished from every other disease by its colour, its situation, the dimness of vision progressing with the increase of opacity; the activity of the iris, the absence of pain and inflammation; and, in its early stage particularly, by the variation in the power of sight, according to the size of the pupil. There are many unnecessary rules laid down for distinguishing cataract from other diseases, but in the majority of instances the distinction will be self-evident. If cataract takes place in advanced life, its

progress is generally slow: the patient complains of a mist before the sight, which is specially inconvenient in the middle of the day, when the sun shines brightly; objects appear smoky to the patient, but are more distinctly seen when placed in an oblique direction. If the iris be put under the influence of belladonna, and the lens be then examined, a somewhat dense spot, generally of an amber colour, will be seen in its centre, the circumference having only partially lost its transparency. No change in any of the other textures of the eye will be discovered; but should any defect of vision beyond what ought to result from the existing degree of opacity be present, an exceedingly attentive examination must be made, and the history of the case closely investigated; it will then very probably be found that amaurosis, glaucoma, or some other disease of the deep-seated textures, exists. Amaurosis is frequently preceded and accompanied by some alteration in the condition of the health, or pain in the head or eye-ball; its progress is occasionally very rapid; it occurs at all periods of life, and is not indicated by any want of transparency in the visual textures of the eye. Glaucoma generally arises from some obviously acting cause, which has been producing a slowly advancing inflammation of the cells of the vitreous humour; peculiar positions of the body; the long continued inspection of objects of the same size and colour; by working at a fire; or by continued study by artificial light. There is commonly some degree of pain in the eye; and on a close examination we find, situated deeply within it, a dingy green mass, with a cupped surface. We find, also, that there is no correspondence between the dimness of vision and the existing degree of opacity; the sight is injured more than it ought to be if the mere alteration of transparency were alone the cause. Amaurosis and cataract may be combined, or glaucoma may be joined with an opacity of the lens; the former, (amaurosis) or the latter (cataract) may be the primitive disease, or they may be coeval. If cataract be fully formed before these diseases commence, the difficulty of distinguishing them may be considerable; but an attentive investigation of the history of the case, and a close observation of symptoms, will, in many cases, guide us to a correct diagnosis. If a patient,

who has cataract in one eye only, complain of being unable to distinguish the light of a candle when the healthy organ is closed, after having been previously accustomed to distinguish a brilliant from a feeble light; and if, on a careful examination, we cannot detect any superficial inflammation, or any augmented opacity of the lens, or any other alteration to account for the change; and if the patient now complain of headache, or pain in the eye, and the opposite organ becomes somewhat dim, without any appreciable want of transparency; and if to these symptoms be added a tardiness not previously noticed in the action of the irides, the nature of the case is sufficiently obvious. If, instead of amaurosis, glaucoma should supervene, the diagnosis would be increased difficulty; for as we cannot inspect the part we presume to be diseased, and as the symptoms are necessarily imperfect and obscure, our opinion must be the result of inference, partaking, in many of these cases, more of the character of feeble conjecture than confident certainty. In such instances (if one eye only be affected) I have found the degree of dimness increased, but vision has not been quite destroyed: the patient will say, I can see an indistinct glimmering, but the perception of light is weaker than formerly. Should the opposite eye be found affected with glaucoma, the source of the mischief is more certainly discovered. If amaurosis or glaucoma be the primitive disease, we shall have the peculiar history of each; and during the progress of the cataract the sight will be equally, or almost equally dim. It is not requisite to say any thing about the means of distinguishing this disease from lymph effused upon the capsule from iritis or choroiditis: a turbid condition of the aqueous humour, or purulent effusion into the anterior chamber; they cannot, I think, be confounded by any person possessing the slightest knowledge of diseases of the eye. The time occupied in the production of cataract is extremely variable: if it take place as the result of local injury, its progress is miraculously rapid; if it arise in the middle period of life, it is somewhat quickly matured; but in advanced life it is very slowly formed, for reasons which will be presently explained: we cannot, indeed, affix a limit to the time the formation of cataract may occupy. In old persons

we find the opaque lens generally of an amber or green colour, particularly in its centre; whilst in early life it is usually white, chiefly in consequence of its lesser degree of density and volume at that period. An opaque spot is occasionally observed in the centre of the lens, a defect sometimes congenital, and more rarely the product of disease; I have never seen it produced by accident. Perfect opacity of the centre of the lens, whilst its circumference retains its entire transparency, is never occasioned by accident, as far, at least, as I have had an opportunity of remarking such an appearance.

I have not observed that endless variety in the consistence and colour of cataract which has been noticed by others: in youth it is generally of a white colour and soft consistence; in old age it has an amber or a greenish tint, and a firm consistence. The healthy lens is characterized by the same grades of firmness at the same periods of life; the variations from these states are too unfrequent to justify any division grounded on the anomaly. When speaking of the varieties of cataract, I acknowledge, as separate and distinct forms of the disease, the capsular, the lenticular, and the capsulo-lenticular. If the anterior capsule only become opaque, it is characterized by its convex figure, its proximity to the concave surface of the cornea, and its radiated or striated structure, or a peculiarly white and uniformly glistening appearance. When this radiated appearance exists prior to any extension of the affection, a quantity of light readily passes through the divisions—the striæ of the capsule, and the patient may have even more than a confused perception of objects. But other parts generally participate in the mischief; the posterior capsule and the lens sooner or later become subject to the same change. When the posterior capsule has lost its transparency, it is distinguished by its shining concave surface and comparatively deep situation: like the former disease, it soon merges into the capsulo-lenticular. Lenticular cataract presents a dense convex aspect; it is situated neither so deeply as the latter, nor so superficially as the former; its centre is of a higher colour than its circumference, and it has no shining surface. To these points of distinction must be added the variable power of vision according to the size of

the pupil, a circumstance seldom if ever noticed when the capsule only is opaque on account of the uniformity of the opacity, the circumference and centre being equally affected in capsular cataract. If this disease arise from accident, it is whiter and softer than when produced in the ordinary way; and is not uncommonly absorbed, being first softened by the liquor morgagni, if the wound in the capsule become quickly closed, (if it be very small this may happen), or, more effectually, by the aqueous humour, if it remain open; and, secondly, absorbed either by the absorbing surface of the capsule, or of the chambers of the eye.

[To be continued.]

CHRONIC HYDROCEPHALUS.

To the Editor of the London Medical Gazette.

SIR,

At a time when the attention of the profession has been particularly directed to the subject of chronic hydrocephalus, by the successful issue of the cases which Dr. Conquest has brought forward, I cannot but think that any thing relating to the subject will afford some interest. From this feeling, and from a conviction that the propriety of puncturing the head in these cases, can only be decided by experience, and that proper experience can only be obtained by a careful comparison of a number of cases, it is that I am now desirous of laying the following case before the profession. Although unsuccessful, I am by no means inclined to attribute the unfavourable termination of the case to the effects of the operation; on the contrary, I think the appearances on dissection fully warrant the opinion, that death would very soon have taken place, if not as soon, had the operation not been performed. That the mere puncture was not the cause of the fatal termination, or of the appearances after death, I also think is pretty satisfactorily proved, by the fact, that no unfavourable symptoms, no symptoms of inflammation, were discoverable until sixty hours after it had taken place. In the account of the post-mortem examination, it will be found that

a slight blush of redness existed around the puncture, but this was strictly confined to the pericranium, the membranes below being entirely free from the least appearance of inflammation; indeed in this, as in every other part, they were unnaturally pale. To what, then, can be attributed the fatal termination? Certainly not to any inflammation induced by the operation, but rather, I should say, to the previous disorganized state of the brain,—a state which, I am fearful, obtains in a great majority of cases, when far advanced. If this view of the subject be correct, it should make us exceedingly cautious in the choice of the cases for operating on, otherwise that which, when used with due caution, may yet be found to be a valuable means of restoring a fellow creature to health and usefulness, may be productive of much mischief. In the present instance, the operation was not recommended without duly considering all the circumstances connected with it, nor without the firm conviction that it offered the only chance of relief. I had hoped, that from the favourable state of the child's health, and the absence of symptoms denoting any extensive disorganization of the brain, that there was a fair chance of success; in this, however, I was mistaken, which I shall regret the less, if the present failure shall have the effect of inducing a proper degree of caution in those in whose charge cases of this description may fall.

For the opportunity of watching the following very interesting case, I am indebted to my friend, Mr. Waterworth, of the New Kent Road; from whom I also obtained an account of the early symptoms. I have been unwilling to occupy more of your valuable space than necessary, and have therefore endeavoured to give as short an account of the case as possible, without omitting any thing important.

I am, sir,

Your obedient servant,

STEPHEN HALL, M.D.

Walworth, May 17, 1830.]

CASE.—E. W. æt. 16 months, at about the age of three months was attacked with convulsions, arising without any very evident cause, and unattended by the usual symptoms of acute hydrocephalus. After a time these convulsions subsided, and the infant remained well until the period of teething,

when they again returned with greater force; always being much aggravated on the appearance of a new tooth;—but between these periods she appeared to suffer no pain, and was cheerful. Shortly after the recurrence of the convulsions at the commencement of teething, it was observed that she had lost the power of the left arm and leg, although these parts continued to be as well nourished as those on the right side. The head was originally large; but from the first attack of convulsions it was observed to increase rapidly in size to the period when I first saw it (February of this year), at which time the greatest circumference was twenty-three and a half inches; whilst another measurement, taken from the upper part of the ala of one ear over the top of the head, to the same part on the opposite side, gave fifteen inches. She now appeared to have suffered very little in health; the body was alike plump both on the paralyzed and sound side, the appetite good, and she slept quietly. There had been no convulsions for some time; the pupils were dilated, but contracted on the admission of light; and there was occasional strabismus. The bowels had all along been torpid, and still continued so.

It appeared to us that this was a fair case for trying the effects of tapping; and as it seemed to afford the only chance of permanent relief, the operation was proposed. The consent of the parents was not given till about two months after this, when I again saw the child (May 1st), and found it exactly in the same state as above described, except that the head had greatly increased since my last visit; the greatest circumference being now twenty-six inches, and the measure across the top of the head, between the points before-named, having increased to eighteen inches.

The next day (May 2d) I met Mr. Waterworth at the residence of the child, in company with Messrs. Clarke and Franks. Mr. W. had provided himself with a sharp-pointed, flattened, straight needle, which gradually became broader towards the part attached to the handle; having a groove on one side, gradually increasing in size in the same manner as the needle. The child being placed on the nurse's lap, with a linen bandage round the head, the needle was passed into the anterior fontanel, about

half an inch to the right of the longitudinal sinus, and immediately adjoining the inner angle of the right frontal bone, in a direction slanting backwards, and there retained. The needle entered about an inch and a half, or two inches, and through the groove a clear fluid continued to flow in a small stream, until two ounces and a half had passed out. A considerable degree of collapse now came on, unaccompanied, however, by any convulsion; when the needle was withdrawn, and a little ammonia in water was given. In a short time the child began to revive, and there was evidently an inclination to sleep. Before we left, the bandage round the head was tightened, and another placed over the now depressed fontanel, passing behind the ears, and under the occiput; after this the child was placed in the cradle, the room was ordered to be darkened, heat to be applied to the feet, and cold spirit lotion to the head, and the most perfect quiet enjoined. When we left, the water was still running from the opening.

On the day after the operation, it was found that she had had some hours quiet sleep immediately after we left, from which she awoke refreshed, and appeared to the father relieved. She had passed a better night than usual, and was cheerful; there had been no convulsion nor unnatural heat; the pupils were dilated, but sensible to the influence of light; the pulse was quick; she had passed no motion, and very little urine, since the operation. She was ordered to renew the use of the calomel and squill, and to take some castor oil, by which the bowels were relieved, and the urine flowed plentifully.

No untoward symptoms manifested themselves, either on this or the following day; but on the morning of the 5th (the third day after the operation) violent convulsions came on, and continued to recur at short intervals until early the next morning, at which time she died.

Inspectio Cadaveris.—On removing the scalp, a slight inflammatory blush only was observed on the pericranium, surrounding the spot at which the instrument had entered, of about an inch in diameter. A large quantity of fluid could be felt fluctuating within the membranes in the course of the separated sutures, the greatest part of which was let out by puncturing the mem-

branes at the anterior fontanel, after which the cranium was removed without losing any of the fluid. When the brain was exposed, it was found exceedingly soft and flabby, the two hemispheres more resembling empty bags than those parts in a natural state. A vertical incision was first made along the centre of the left hemisphere, from before backwards, which laid open the whole length of the ventricle on that side, enormously distended: the walls, although pale and very soft, were firm compared to those of the opposite side; there was also very little blood in plexus choroides. The thickness of the cerebrum above this ventricle was no where more than the third of an inch, and in many parts not so much. On opening the right ventricle, no trace of the original conformation could be discovered; the whole substance of the brain surrounding it was softened down to the consistence of cream or pus, and in many parts nothing but a membranous bag could be found. On the floor of the left ventricle the parts were with difficulty recognised; whilst on the right it was utterly impossible to do so, so completely were they disorganized. The base of the brain and cerebellum appeared healthy, and tolerably firm. Very little blood was found either in the vessels of the brain or membranes. The fluid found in the head measured exactly a quart: neither this, nor the fluid which was drawn off during life, coagulated on the application of heat.

DUTY ON THOSE ENTERING THE MEDICAL PROFESSION.

To the Editor of the London Medical Gazette.

SIR,

I HAVE long entertained the opinion that no measure would so effectually tend to heighten the respectability of our profession, as the imposition of a duty on those entering it. I have long watched for an opportunity of canvassing this question in public, and have constantly agitated it in private, among my own immediate professional acquaintances; hoping that some person better qualified to command attention might bring the subject on the tapis.

But as the heads of the Government

have now taken into consideration a tax of a nature not altogether different, I think the present opportunity too critical to be lost for the want of a better advocate, and shall therefore submit to you some of the more cogent reasons that have influenced me in forming this opinion.

I suppose there are very few so absurd as to maintain that the members of our profession are not at present very numerous. It is a common observation, that every third or fourth house belongs to an apothecary or surgeon. The fact is so obvious that I need not waste time in attempting to prove it, therefore I shall at once proceed to shew that this is an evil of the greatest magnitude, and exerts a most baneful influence on the profession and public in general; a point not quite so clear, perhaps, though equally true. If the number of practitioners is great, it follows that the patients which fall to each individual's share must be few; and as the profits are in an exact ratio to the extent of their business, the individuals generally must be poor. It is from this cause that medical men are ill paid; not that the public are not sufficiently liberal, but that each practitioner has too few patients to occupy his time and yield him that remuneration which would place him in his proper sphere of society.

Such is our case; but the public suffer equally with ourselves. It was long ago demonstrated that too many attorneys were a great evil; business became so divided, and profits so reduced, that persons of respectability would not enter this profession; therefore property became entrusted to a class of persons of equivocal character, and much imposition and fraud were the results. We have the charge of the lives, in the same way as the attorneys have the care of the property of the citizens of the state; and in both cases probity as well as talent is requisite, and the more so among the practitioners of physic, since it must be confessed that the public, however enlightened by a modern course of education, are yet too ignorant of the mysteries of our art to form a correct estimate of the qualifications of those whom they employ in this department.

When a person without property attempts to study medicine, obstacles beset him at every step: in the first place,

he is obliged to abridge the time required to learn the science within the smallest compass that our chartered bodies permit, and too frequently certificates are obtained for an attendance on lectures and hospitals that has been, in truth, merely nominal: for instance, some time since, when I was about to engage an assistant, he wished to stipulate to be allowed to shew himself (that was his phrase) for an hour, once a week, at an hospital, to which he had entered himself a student. This young man might be very studious, and desirous of acquiring a knowledge of his profession, but how was it possible that he should ever attain it by such a proceeding? he might, indeed, have been able to scrape together from the various manuals that are published, a sufficient quantity of verbal information to pass a verbal examination; but how would he act when brought to the patient's bedside? perhaps, in the first instance, he might be tempted to confess his ignorance, but finding that disgrace alone was the reward of his candour, he would next consider how he should gain a livelihood. The answer to this question is what I fear but too frequently happens: finding that it will not answer his purpose to make such a confession, he begins by making his patients believe, that he understands the nature of their complaints; the next step is, to make himself believe that he knows as much as any other person,—this belief, so flattering to his vanity, very soon gains credence, and thus confidence being added to ignorance, the door is shut against any further improvement.

Now, sir, it is not the present tax that can obviate this mischief; but let a stamp duty, not of a trifling ten pounds, but of one or two hundred, be placed on the articles of indenture, and we shall at once strike at the root of the evil, by preventing those who have not the means from ever attempting to enter the profession. The apprentice would then be a person qualified by previous education for the more arduous studies of our science; he would come to it with a mind inured to patient investigation, and well stored with that knowledge of the dead and living languages, which undoubtedly will greatly facilitate his progress. After the term of his apprenticeship was expired, he would have the means to attend an hospital,

devoting his whole time to it, and not merely paying it a casual visit once or twice a week, as is too often the case at present; and he would be enabled to do this just as long as might be necessary to teach him all that he ought to understand, and not for the precise term prescribed by the College of Surgeons or the Apothecaries' Hall.

If this were carried into effect, multitudes would be prevented from embarking in this profession, and its numbers would be so far diminished as to allow each individual, with common diligence and application, to obtain a sufficient share of practice to yield him an honest independence, which, together with his improved education, would afford the public the best security for his integrity and ability.

I am, Sir,
A SURGEON AND APOTHECARY,

ANALYSES & NOTICES OF BOOKS.

“ L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

Analysis of the works of Dr. S. Smith and Dr. Tweedie on Fever.

[Continued from page 310.]

ART. III.

OF THE THEORY OF FEVER.

OUR author's theory of fever will appear from the following summary, given in his own words:—

“ The immediate cause of fever is a poison, which operates primarily and specifically upon the brain and the spinal cord. The diseased state into which these organs are brought by the operation of this poison, deprives them of the power of communicating to the system that supply of stimulus which is requisite to maintain the functions of the economy in the state of health. The organs, the seats of the functions, deprived of their supply of nervous influence, become deranged, the derangement in each taking place in a fixed order, and in a determinate manner. Subsequently to the nervous and the sensorial, the organs the next to suffer are those of the circulation; then

those of respiration; and, ultimately, those which belong to secretion and excretion. The condition of the nervous system which produces this derangement in this circle of organs, occasions further, in that portion of the circulating system which consists of the capillary bloodvessels, that peculiar state which constitutes inflammation; hence, inflammation is almost always established in one or more of the organs comprehended in the febrile circle, and sometimes in all of them. The peculiar and primary affection of the nervous system, which is here assigned as the cause of inflammation, does not become identical with inflammation, but superadds the morbid condition of inflammation to its own; does not lapse into or terminate in the inflammatory state, but accompanies it, and by this combination modifies in a peculiar manner the inflammatory process."—P. 346.

Differing from Dr. S. in so many respects as we have done, we are truly glad of the opportunity to concur with him in the opinion, that the brain and nervous system are the organs first ostensibly affected in fever, and that most of the phenomena and events which subsequently present themselves, arise out of this affection; but we are not prepared to say with him, that the poison of fever operates primarily and specifically upon the brain. This opinion of our author is not upheld by proof, nothing being advanced in support of it; it is, indeed, a bare assertion. Had he intended seriously to maintain this doctrine, it would have been incumbent on him to shew that a poison conveyed by the atmosphere acts directly upon the nervous system, but the subject is not even discussed; and what is singular, he supplies, in another part of his work, a formidable evidence against his own opinion, and in favour of the poison of fever acting primarily upon the blood; for at the conclusion of the chapter "Of the Remote or Predisposing Causes of Fever," he gives a very interesting account of some experiments performed by Dr. Potter, which testify, in the most unequivocal manner, that in persons exposed to the poison of yellow fever, the blood becomes in a morbid condition, while to external appearance and inward feeling these persons were in sound health; and moreover, that this morbid blood could in no respect be distinguished from the blood of those who

laboured under the most intense forms of the prevailing fever.

"In these experiments the blood in six persons indicated the operation of the morbid cause, while each remained in a state of apparent health. Of these six persons four were actually seized with yellow fever during the prevalence of the epidemic; and the other two, though they escaped any formal attack, did not escape indisposition. The diseased blood was of a yellow or of a deep orange colour, and a portion of the red particles was invariably precipitated. This blood was compared with blood drawn from an equal number of persons who dwell on the hills in Baltimore country, where the atmosphere was unquestionable pure; the serum in these instances was neither of a yellow, nor of an orange colour; there was no red precipitate; the appearances were such as are found in the blood of persons in perfect health."

For consistency-sake, the Doctor should not have brought forward this posing contradiction to his frequent assertions, that the poison of fever acts primarily upon the brain, and that there is no evidence of a morbid condition of the blood in fever!

The observations on the non-identity of fever and inflammation are very apposite; not so, however, are those on the subject of inflammation as connected with fever. After some laboured reasoning upon facts which are partly unquestionably, partly assumed, our author concludes "that the second event that takes place in the morbid series constituting fever, is inflammation."—p. 338. In arriving at this conclusion, the Doctor has evidently experienced great embarrassment, which could not but be the case with any one who, like himself, has indiscriminately put down whatever morbid changes he may have met with as having occurred during the fever. The basis of his opinions rests unquestionably on the dissections detailed in the work, which we have shewn are not satisfactory as relates to fever. In fact, the Doctor does not discriminate between the lesions of diseased action prior to the fever, and those which take place during its progress: and concluding as he does that all the changes of structure, and all the new products which he has met with in his dissections at the Fever Hospital, have been generated during the fever, and inflammatory ac-

tion being a necessary agent in these changes and products, the origin of the author's opinion, that inflammation was the "second event," becomes sufficiently apparent. But what will be said of those numerous cases of protracted fever in which the patients recover without any of the consequences which are known to succeed organic inflammation, as lesion of function? What will be said of those protracted cases which eventually prove fatal, and in which the organic changes and morbid products are trivial, or only what are found under the ordinary circumstances of a lingering death? What will be said of cases in which the patient has met with an accidental death during the height of the fever, and yet dissection revealed no organic inflammation or disease*? Why the unavoidable inference is, that inflammation is not a necessary event in any case of fever, but that it may be an accidental adjunct or accompaniment.

There are two exceptions to the Doctor's theory which he anticipates, *viz.* "the very mildest and the very severest forms of fever" in which inflammation is not the second event, there being no indication or proof of its existence. These exceptions cannot be got over—they are millstones about the neck of the theory.

The Doctor agrees with some other recent authors, that the inflammation is modified by the state of the nervous system, and to this position we can add our support.

The function which comes next under notice is the respiratory, which the Doctor affirms must become involved as a consequence on the derangement of the circulating system, and that "the function of respiration cannot be materially deranged without producing a morbid condition of the blood," and that disordered secretion and excretion must attend the derangement of the systems before mentioned. There is here some indistinctness, and no detail as to the manner in which the respiratory function becomes deranged, but as pathology is referred to as demonstrating the fact, the reference must of course be to the bronchial affection, which is the ground Dr. Armstrong rested upon in his explanations of the

morbid condition of the blood, and it would have been more candid in Dr. Smith to come boldly forward as an approver of Armstrong's doctrine, than beat about the bush to arrive at the same end. We ourselves do not approve of the explanation of Armstrong, believing that the blood is much earlier affected, and that whatever bronchial affections there may be, it acts only as a secondary cause.

We quit theory to say a few words in commendation of the succeeding chapter on the causes of fever, in which are collected and well put together some very interesting particulars relative to the origin and generation of the poison, which is now well ascertained to be the cause of fever in various climates. Our readers will peruse this account with much gratification and profit, as we have done ourselves, and we regret that the matter does not admit of condensation in the form of an abstract. The author's opinion is pretty decided as to the generation of the poison being from the decomposition of animal rather than of vegetable matter.

OF THE TREATMENT.

The consideration of the last chapter will detain us longer, as our sentiments are much at variance with Dr. Smith's on the subject of the treatment. In the composition of this chapter the author has put forth all his strength; his mind is on the stretch, and his imagination glowing; and no wonder we should have a production truly Quixotic, the subdual of inflammation being the object of his chivalrous exploits.

It is not enough to paint his opinions in strong colours; they must be supported and enforced by digressive similes and illustrations: the sober language of science is not in concert with our author's fervour; the figurative epithets of poetry, and the sounding polysyllables of declamation, are alone congenial. In this strain we find him speaking of "*precious moments*"—"the golden opportunity"—"*a masterless enemy*"—"obtaining the victory"—"*promptly*"—"boldly"—"*most imminent risk*"—"a disease of frightful power"—"*nurtured to maturity*"—"the most extreme caution," &c. &c.

* Such a case is recorded by Andral or Louis, we forget which.—*Ret.*

After a few preliminary observations,

Dr. S. affirms, that "the only morbid condition of fever, of which we have any knowledge, and over which the medical art has any control, is that of inflammation," p. 376; and "the object to be aimed at in practice, then, is clear: it is to prevent, or to remove inflammation." p. 379.—"If excitement be set up in an organ which has as invariable a tendency to terminate in inflammation as a stone to fall to the ground, what is the proper remedy to prevent the transition of excitement into inflammation? Bleeding," p. 380.—"Bleeding in fever cannot be performed too early. The very first moment of excitement, could that be discovered, is precisely the moment when the employment of this powerful remedy would produce the greatest effect." p. 382.

We cannot call to mind any work, the perusal of which requires more caution in investigating the grounds on which a position is advanced than the one before us. We may take the opportunity of reminding our younger readers to look well, on all occasions, to the materials which form the basis of any principle laid down, because an author may steal a march upon them by dexterously arriving at a certain position, which, being once obtained, all that follows comes as a matter of course, and in so fair a garb that it cannot but be admitted. In the present instance, for example, Dr. Smith insists that inflammation is the second event in fever, and for the proof of the existence and ravages of inflammation, he refers to the "hundred cases," in the greater part of which it is manifest that inflammation has been the active agent in organic change and destruction. If the reader inquires under what circumstances did this inflammation take place, Dr. Smith's answer is, fever. We will do the Doctor the justice to believe that this is his own sincere opinion, and as such he urges it upon others; and this opinion, once admitted, it follows legitimately that blood-letting is the best means of averting or subduing such inflammation. We trust our readers are already disposed to call in question, if not to reject the position of inflammation advanced by Dr. Smith, from the facts and arguments we have already adduced in other parts of this review, but the point is one of so much consequence that we feel it our duty to pursue the subject further.

Is inflammation, then, so invariably

the second event in fever as our author affirms? We answer, no. Are the consequences of inflammation, when it does occur, of so serious a nature, and is it of such an intense character generally as our author affirms? We answer, no. And, in accordance with this answer, we further add, that blood-letting is not called for so frequently, or to the extent that Dr. S. recommends.

We have admitted that inflammation was the active agent in producing the organic changes exhibited in the "hundred cases," but we deny that such inflammation existed, or that such changes took place generally during the course of the fever, and for the following reasons. The Doctor admits "that febrile inflammation, and ordinary inflammation, are not identical;" that "febrile inflammation is a modified inflammation, the modification consisting in less activity in the vascular system, and greater depression in the nervous." To these opinions we subscribe most fully, but we ask, can this febrile inflammation, with less activity in the vascular system and greater depression in the nervous, give rise to the same morbid products and changes as ordinary inflammation, which consists in greater activity in the vascular system, and no depression in the nervous? Certainly not, or else the nervous and vascular systems have nothing to do in determining the products of inflammation. The products of febrile inflammation, then, must differ from the products of ordinary inflammation, which no one can doubt who has studied pathological anatomy. But what says our author in another part? "Almost every change of organic structure which inflammation is ascertained to be capable of producing, is found to take place in fever; almost every product which inflammation is ascertained to be capable of forming, is observed to be generated in fever," (p. 338). Here this modified inflammation is said to be capable of giving rise to all the changes and products of an ordinary inflammation, which is impossible.

This erroneous opinion of our author arose from considering all the morbid products and changes which he found in persons who died of fever as having taken place during the course of that fever, and as being consequently the result of the modified febrile inflammation; whereas many of those products and

changes were the result of an ordinary inflammation at some time antecedent to the attack of fever. For example, if a person has an attack of pneumonia, which leaves one or more lobes of the lungs in a state of hepatization; and if this person in a year or two afterwards has an attack of fever, of which he dies, this hepatization would be considered by Dr. Smith as having occurred during the fever, and, consequently, as being the product of the modified febrile inflammation; whereas it was the product of an ordinary inflammation at a former period. Here is the grand source of error on the part of our author, which has led him to believe, and to affirm, that inflammation is invariably the second event; and then comes the dangerous inference, that bleeding is the remedy. No instance can better exemplify the caution which should be used in making good the ground as we proceed in our inquiries; for one error at the outset is fatal to all that follows, and is dependent or erected upon it; it is building a house upon the sand.

Under the unfortunate conviction that inflammation is the great enemy to be mastered in the treatment of fever, and that bleeding is the only means, our author proceeds to urge the use of this remedy rather by reasoning and inference than by practical evidence.

After recommending the abstraction of blood in the first moment of excitement, as we have quoted, Dr. S. goes on to observe:—"When inflammation has actually come on, there is then not a moment to be lost; that inflammation must be stopped; the accomplishment of this object is the great end which the practitioner should aim at in every thing he attempts; until he has done this, he has done nothing; until he has done this, he ought to give neither sleep to his eyes, nor slumber to his eyelids; until he has done this, he ought to feel that there should be no rest for himself, because there is no safety for his patient. Until the inflammation is subdued, blood must be taken, be the quantity it may be necessary to abstract, in order to accomplish this object, what it may; be the bleedings it may be requisite to repeat what they may, the vein must be allowed to flow, and it must be opened again and again until this object is secured. If this golden opportunity be allowed to escape, and this object be not obtained, the risk is most immi-

nent."—p. 382. What does all this preaching mean? Does the Doctor forget that he is addressing his professional brethren? or does he suppose they are to be led away by the effervescence of his heated imagination? Is the Doctor ambitious to play over again the farce which was played by his predecessor, Armstrong? Where are the instances of inflammation in fever which run their course, as the Doctor would lead us to believe, as swiftly as the cholera of India, or are as quickly fatal as a strangulated hernia? One would suppose that fever patients were apt to be cut off in twenty-four hours by an inflammation! What is the fact? what is the evidence of practical and sober-judging physicians? Why that generally speaking a moderate abstraction of blood only is necessary, and that the inflammations attending fever are, for the most part, of a subacute, and rarely of a violent character. Such are the sentiments of Stoker, Bright, Burne, and many others.

Now after extolling bloodletting in this vehement manner, our author, thinking probably he may have gone too far, begins to draw in his horns (how like Armstrong!) by saying, "That after all, the quantity of blood it is necessary to abstract is not large;" and that "smaller bleedings will subdue febrile than pure inflammation."—p. 384. This brings to mind the trick of Lord Byron, in his beautiful poem, *Don Juan*, where, after having worked up the feelings of his readers to the greatest point, he turns round and laughs at them.

Our readers will scarcely be prepared to learn, that, notwithstanding what the author has urged on the necessity of bleeding to subdue febrile inflammation, he confesses that blood-letting has little or no control over the thoracic and abdominal affections. He says, "in the severe bronchial affections of fever, blood-letting is of little avail. It seems to have scarcely any control over the peculiar affections of the lining membrane of the bronchial tubes, or even over the inflammation of the substance of the lining, which so often accompanies the intense form of thoracic disease." p. 403. And also, with respect to the abdominal affections, he says, "general bleeding has but little influence over the disease." p. 405. So that, of the three affections—the cere-

bral, the thoracic, and abdominal—the nature of all of which is *inflammation*, *two* of them are not controlled by bleeding. How are these contradictions to be reconciled? Is, then, the cerebral affection the only one to which all the earnest recommendation of blood-letting is applicable? If so, the author leaves us at a loss even here to assure ourselves what are the indications which assure us of the existence of the cerebral affection; seeing that, in the case of Potter, which he considered to be an intense cerebral affection, the brain was found on dissection to be healthy!

After blood-letting, all other remedies sink into insignificance. Calomel and rhubarb, as well as castor-oil, are mentioned as proper purgatives. Wine and brandy are allowed when life is fast ebbing; and opiates under particular circumstances. The treatment at the Fever Hospital appears to continue much as Dr. Armstrong established it; a routine of bleeding, rhubarb and calomel, and castor-oil. We hasten to conclude this long analysis, of which our readers as well as ourselves are, we dare say, heartily tired, by some observations on Dr. Dill's extraordinary case, which probably has no parallel in the records of medicine.

The case of Dr. Dill demands our most serious attention, and deserves that of our readers. It is adduced as an example of severe cerebral affection; in which cases, Dr. S. affirms, "the bleeding must be proportionally large and early as it is copious."

"I saw him," says Dr. Smith, "*before there was any pain in the head, or even in the back; while he was yet only feeble and chilly. The aspect of his countenance, the state of his pulse (which was slow and labouring), and the answers he returned to two or three questions, satisfied me of the inordinate, I may say the ferocious attack that was at hand.*" p. 398.

Whatever may be the opinion of our readers, as to the above signs indicating a ferocious cerebral attack, they will one and all agree with us, that the ferocious attack was met by a ferocious treatment; for an emetic was given without delay, and "blood was taken from the arm to the extent of *twenty ounces.*" This blood was not inflamed. Severe pain in the limbs and loins, and intense pain in the head, came on during the night, and early in the morning

blood was again drawn to the extent of *sixteen ounces*, "with great diminution but not entire removal of the pain." Towards the afternoon he was again bled to *sixteen ounces*: "the pain was now quite gone; the blood from both these bleedings intensely inflamed."

During the night the pain returned, and in the morning, notwithstanding the eyes were dull and beginning to be suffused, the face blanched (no wonder!) and the pulse slow (?), and intermittent and *weak*, *twelve* leeches were applied to the temples, and as these did not entirely remove the pain, more blood, to the extent of *sixteen ounces*, was taken by cupping. This operation afforded great relief, but the following evening the pain *returned*, and again was blood abstracted to *sixteen ounces*. "Immediate relief followed this second operation; but *unfortunately* the pain *returned* with great violence towards evening, and it was now impossible to carry the bleeding any further." Typhoid symptoms now began to shew themselves, "the fur on the tongue was becoming brown, and there was already slight tremor in the hands." What was to be done? Ice and evaporating lotions were of no avail; but happily for Dill, the affusion of cold water on the head, "the cold dash," was thought of and employed; and this being effectually applied, "the relief was instantaneous and most complete." So that this case, announced as a severe cerebral affection, and treated in anticipation by copious blood-letting, *before there was any pain in the head, while the patient was yet only feeble and chilly*, which grew worse and worse as the blood-letting was repeated, until, after the abstraction of *ninety ounces* of blood, the patient had become in "a state of intense suffering" and "imminent danger," and was relieved at last by "the cold dash"; this case, we say, is brought forward as a specimen of the extent to which copious bloodletting may sometimes be required!!! Most sincerely do we congratulate Dr. Dill on his escape, not from a dangerous disease, but from a dangerous remedy.

Now in this case the Doctor had a fair, a "golden" opportunity, of carrying into effect the precepts he enjoins as to early and copious blood-letting; and what was the result?—not an effectual relief, not even a mitigation of the symptoms! On the contrary, intense

pain in the head followed the first bleeding, and after every abstraction of blood the patient grew worse and worse, till at length he was brought to a "state of imminent danger" and "intense suffering;" *to a state in which, "without the aid of some powerful remedy, the case was lost!"* Typhoid symptoms had begun to shew themselves, and no more blood could be taken with safety. But how does this tally with the rules of treatment laid down only a few pages before?—where the repeated abstraction of blood is urged "until the pain, wherever seated, be entirely removed;" where it is said, "nothing is more common than the appearance of typhoid symptoms on the second or third day after bleeding has done nothing but lessen the inflammatory action; whereas, had it been carried somewhat, and generally only a little farther, the patient would have been convalescent at the very period when his dangers becomes most imminent." p. 386. The case before us was precisely the one in which, in conformity with the Doctor's own injunctions, blood-letting should have been carried "*a little farther,*" until the pain was entirely removed; and what would have been the consequence? Why, according to the Doctor's own shewing, the patient would have been removed as well as the pain. This contradictory precept and practice needs no comment.

Now the principle on which Dr. Dill was treated, as laid down by our author, is as follows: "The only morbid condition of fever of which we have any knowledge, and over which the medical art has any control, is that of inflammation." Inflammation, then, was the affection which the Doctor had in view to prevent or to subdue; and now comes the question, was there inflammation? Did the signs indicate an attack of inflammation? There certainly was no inflammation at the period when the blood-letting was commenced, for "he was yet only feeble and chilly," and altogether free from pain. Nor was there, in our humble opinion, any manifestation of a pending or threatening cerebral inflammation. The being feeble and chilly may be the effect of cold, and is in no way diagnostic as a precursor of any particular complaint; and the confusion of mind, on which much stress is laid, is a very common occur-

rence in the cold stage of an intermittent, and therefore not to be relied upon as diagnostic of an attack of "an intense form of fever;" nor can it be wondered at that the pulse was slow, and that the patient sighed deeply. What medical man would not sigh, and feel confused, under the impression of an attack of an intense form of fever, that impression being heightened by the "ferocious" treatment commenced in anticipation? To us the effects of fear are very visible in the confusion of mind and "death-pale countenance," and slow pulse; a state just short of fainting, and one likely to happen to a professional man, the inmate of a fever hospital, who, feeling suddenly feeble and chilly, would naturally take alarm, and dread an approaching fever.

But let us compare the effects of the treatment with the view taken by Dr. S. Although no pain was present when the treatment commenced, it became intense after the abstraction of twenty ounces of blood; and although afterwards relieved for the moment, as every pain is, by blood-letting, still it returned and returned, till, "*unfortunately,*" after having drawn blood till no more could be taken with safety, the patient had become in a state of "intense suffering and imminent danger." Was this tremendous loss of blood, then, beneficial? To us it is evident, as it will be, we are persuaded, to every practical man, that the state of imminent danger was rather the effect of the blood-letting than of the disease. Has Dr. Smith yet to learn that the pain in the head, which is so generally the precursor of an attack of fever, is *aggravated* by general blood-letting? We can assure him of the fact, and were commend it to his serious attention. Surely he must know that many pains in the head, which depend more on the nervous than on the vascular system, are aggravated by loss of blood, although they may be relieved for the moment; and this deceptive relief is the only motive we can assign for perseverance in drawing blood in Dr. Dill's case. Will Dr. Smith venture to put in practice an active and dangerous treatment on the evidence of one sign—pain? It is an error into which a sanguine student may fall; but a physician, of mature age, should at least act with more caution, if

not with more judgment. On this single case, too (no other is adduced or alluded to), is founded a diagnosis, that a slow and intermitting pulse "is characteristic of an exceedingly acute attack of cerebral disease, and one with the import of which it is of the highest consequence to the life of the patient that the practitioner should be perfectly acquainted the moment he meets with it." p. 108. "Whenever, in the onset of fever, a patient is found with intense head-ache, or intense pain in the back and loins, and a *slow pulse*, the physician ought to be greatly alarmed at the severity of the symptoms that are to follow; and if he do not take the most active measures to break the violence of the disease at this early period, it will be beyond all control in a day or two, and the patient will be dead before the fever is well found in milder cases." p. 109.

We should be glad to have an example of the above. In the case of Dr. Dill there was intense pain in the head, and there was a slow pulse; but the disease did not prove fatal in a day or two, nor was its violence broken by the most active measures persevered in as long as they could be with safety. Either then the measures are ineffectual, or the alledged indications of an alarming disease are not to be depended upon;—and yet on the strength of these indications is the diagnosis founded, and on the diagnosis a violent and dangerous, though at the same time an ineffectual, treatment.

The work concludes with some sensible remarks on the "Treatment during the convalescence," which we have much pleasure in recommending to the attention of our readers. "The mismanagement of the convalescence consists (says Dr. S.) in allowing the patient to rise too early from bed, and to take solid food too soon and in too large a quantity; and these are by far the most frequent causes of relapse. Were I to place on record all the instances I have seen of fatal relapse from these two causes alone, the list would be *frightful*." p. 420.

Relapses appear to be very frequent, and convalescence tedious, in the Fever Hospital. We ourselves have always observed that *convalescence is tedious*, and *relapses are frequent*, in proportion as the patients have been reduced by the

loss of blood; which fact we beg to offer to the consideration of Dr. Smith.

Several tables are appended, which present some useful details; but which, to our surprise, do not exhibit the ratio of mortality. The mortality at the Fever Hospital must, we presume, be great, if we judge from the number of dissections which are put down; and also from a table headed "Relation between date of attack, admission, and death, *for one year*, comprehending *eighty-four* cases. 'This great mortality may fairly be attributed, in part, to the circumstance of patients being sent into the hospital in an almost moribund state.

It remains for us to inquire whether any of the opinions advanced by our author can claim to be original.

Those of our readers who are intimately acquainted with the work on Typhus Fever, which introduced the late Dr. Armstrong suddenly to notoriety, will not have failed to remark the correspondence between it and the one under review. So exactly, indeed, do they tally, that the one appears to us to be little else than a version of the other; for not only are the particular opinions adopted, but also the main distribution of the subject, and on some occasions even the expressions; and all without a single allusion to the deceased original. Much as the opinions coincide, there is, nevertheless, a striking contrast in the redundant, gorgeous, laboured, declamatory style of our author, and the fluent, elegant, and persuasive language of Dr. Armstrong. Dr. Armstrong insists on the frequency and importance of inflammation in fever, and on this view founds his variety, *inflammatory typhus*, under which head he treats of *cerebral, thoracic, and abdominal inflammations, sub-acute and acute*; Dr. Smith goes a little further, and insists on inflammation being the *second event* in fever, and treats of it also under the divisions *cerebral, thoracic, and abdominal, sub-acute and acute*. Dr. Armstrong speaks of *fever passing into inflammation*—Dr. Smith adopts not only the notion, but the very expression. Dr. Armstrong contends that the plague, the yellow fever, the typhus, the remittent, the intermittent, were all varieties of the same thing, produced by a malaria of different degrees of intensity or concen-

tration—so contends Dr. Smith. Dr. Armstrong ridicules the notion of *debility*—so does Dr. Smith. Dr. Armstrong abuses Cullen—so does Dr. Smith. Dr. Armstrong contends that the changes in the blood are produced by the *bronchial affection*—so does Dr. Smith. As to the treatment, Dr. Smith's notions of the necessity and good effects of blood-letting are precisely those of Dr. Armstrong, urged with still more indiscretion. Dr. Armstrong used to introduce in his lectures some extraordinary case, where an immense quantity of blood was required to be abstracted; the same thing has been done by Dr. Smith, in the case of Dr. Dill. But Dr. Armstrong, with more prudence or less sincerity, represented the bleeding as all-efficient—Dr. Smith suffers it to appear that his patient grew worse as blood was drawn, and that another remedy saved his life.

This very singular coincidence of opinions brings to our recollection an article published in the Westminster Review several years ago, which was said to contain the facts and opinions of Dr. Armstrong on Contagion, without any acknowledgment of the source from whence the reviewer obtained his information. What Dr. Armstrong might have done had he yet lived, it is impossible for us to say; but whatever cause he had to be dissatisfied with the reviewer, the same, as it appears to us, he would have had to protest against the adoption, in the work before us, of all those opinions on which he founded his reputation. We do not agree in those doctrines, it is true; and in endeavouring to refute Dr. Smith, we have been arguing against Dr. Armstrong. Had the work not been lauded elsewhere “in praises hyperbolical,” probably we should not have entered so fully into the discussion; and much as we differ from Dr. Smith and those who agree with him, he may so far at least regard our notice as complimentary, that had we regarded his work as unimportant, our analysis would have been much less elaborate.

In another number we shall give an account of the work of Dr. Tweedie.

MEDICAL GAZETTE.

Saturday, May 29, 1830.

“*Licet omnibus, licet etiam mihi, dignitatem Artibus Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.*”—CICERO.

THE KING'S HEALTH.

WHEN we last had occasion to advert to the lamented illness of the King, we stated that the circumstances attending it were such as to leave but little hope of the complaint proving transient. Since that time, the evacuation of a large quantity of serous fluid has produced a great diminution of the swelling and an abatement of the most urgent symptoms; but the dropsy being unfortunately dependent on thoracic disease, its entire removal would not reach the root of the evil, nor prevent the constant tendency to the recurrence of effusion.

The public papers have, on many occasions, censured the reserved and guarded style of the bulletins which have been issued by the royal physicians, and, without expressing any opinion as to the extent to which the medical attendants ought to enter into details, we shall content ourselves with remarking that those who are most ready to blame are not always best informed as to the peculiar disadvantages under which the bulletins have been indited; while the lingering nature of the disease, and the variations it has already undergone, are sufficient evidences of the caution that is required in their construction. One individual has gone farther, and made some statements which we might suppose were merely the result of ignorance, were it not for the appearance of vexation and pique which they display. Thus Sir Henry Hallford and Sir M. Tierney are charged with incompetency; the former being designated “a very respectable gentleman,” but not com-

ing within the class of "scientific physicians;" and the latter, who has been for many years the professional adviser of his Majesty, and attended him in many severe illnesses, is declared to be a person utterly unknown. The absurdity of these allegations is too obvious to require their refutation; but when the writer ventures to assert that a "dangerous and often fatal operation" has been performed on the King, without the name of the surgeon appearing, or the slightest allusion being made in the bulletins to so important an event, we feel called upon positively to contradict so gross a mis-statement.

The "puncturing," which is spoken of in such formidable terms, consists in insinuating through the distended skin a very fine needle, the wound of which is so minute as scarcely to be seen, while its infliction is attended with no pain whatever. As an "operation," indeed, it is about as insignificant and bloodless as pricking the vesication of a blister. The danger which attends these cases depends entirely on the languid state of the circulation, and on the excessive tension of the parts which the puncturing is intended to remove. Thus in the case of his late Royal Highness the Duke of York great distention of the lower extremities took place, and ended in the mortification of a considerable part of the integuments—no scarification or puncturing having been adopted. It was for this local affection, and not for the *medical* part of the case, as erroneously stated, that the assistance of Sir Astley Cooper was on that occasion required. In the case of his Majesty, while the distention remained, there was of course risk of a similar result, and considerable anxiety was at one time caused by the scarifications, which, as we mentioned in a preceding number, had been made at an early period, becoming inflamed; but the tension having been entirely re-

moved by the use of the acupuncture needles, as adopted by Mr. Brodie, we are happy to say that the inflammation has been so much subdued as to remove all apprehension on that head.

We should not have thought of entering into these explanations had not an attempt been made to increase the anxiety, already so great, and to sow distrust in the public mind with regard both to the competency and honesty of his Majesty's medical attendants, in an article which, from having been copied into the "Times," acquired a degree of notoriety and importance which it could not have attained by its limited circulation among the members of the medical profession, who besides fully understand,—though the public cannot,—the feelings of disappointment in which it originated.

COLLEGE OF SURGEONS.

WE are glad to hear that an investigation has taken place as to the conduct of the Beadle of the College of Surgeons, in receiving money from gentlemen desirous of undergoing examination. The consequence has been, his suspension from office. Another petty abuse was the custom of demanding five shillings for the diploma before its delivery—as well as *requesting* some gratuity for the tea and coffee with which the candidates are supplied when waiting to be sworn in. We understand that hereafter the diploma is to be delivered at the Secretary's office, without any fee;—as to the refreshments, it has always been against the rule for the servants to receive any remuneration for them. With regard to the diploma, the old regulation was bad: the beadle was allowed, if he carried it to the member's house, to receive five shillings, if offered—but not to demand it as a right.

PHRENOLOGY IN IRELAND.

IT is a remarkable fact, that the phrenological system has never till very lately obtained any successful footing in the sister island. Several years ago,

we recollect, Dr. Spurzheim proceeded on a mission to enlighten the natives: he was listened to for the moment with courtesy and attention, but he made no converts. Of late, however, symptoms have occasionally manifested themselves indicative of a desire that the Doctor would go over, and expound his doctrines. He was, in short, persuaded to comply, and there he actually is, at this present writing, in the island of saints, charming the faculties of the inquisitive. His first course is over, and a second is in progress. The former was a decidedly popular course of lectures: it was delivered to a class of upwards of three hundred persons, a large proportion of them females, and stranger still, the majority of them individuals of a religious caste. What congeniality or coincidence they discover between their principles and those of phrenology, we shall not pretend to say; but such is the fact; Dr. Spurzheim has delivered, with great applause, a series of lectures on his favourite topic to a class of auditors such as we have described.

He is now engaged at the Park-Street School, in Dublin, delivering a more strictly professional course to a medical class of about ninety gentlemen, who hear him on the anatomy, physiology, and so forth, of the brain. Judging from the high satisfaction which we find expressed by those who have attended and are attending Dr. Spurzheim in Dublin, we should conclude that he will leave behind him some zealous proselytes in that capital.

ARMY MEDICAL INSTITUTIONS.

THE annual meeting of the Medical Officers of the Army was held, at the Thatched-House, on the 19th instant. The reports, both of the Association for Mutual Assurance and of the charity for Orphans, were highly satisfactory, shewing them to be in a flourishing condition, and established on a secure basis.

We may, likewise, take the opportunity of stating, that the library and museum, at Chatham, continue to increase. During the last year, the library has received an addition of not less than 300 volumes, chiefly by donations and by authors presenting their works. It has been found necessary to remove the

collection in natural history to separate rooms, the anatomical museum and library entirely occupying the building fitted up for them. Another very important benefit which the public owe to the Medical Department of the Army, is the collection of a great mass of valuable information regarding disease as it prevails among our troops, as well as histories of the epidemic and endemic maladies of our foreign settlements. We are not aware of any other source whence the same kind and extent of information can be obtained; and it is highly to the credit of Sir James M'Grigor, the present Director-General, under whose auspices these various collections have been formed, that we are enabled to add, that the library and museum at Chatham, and the record-room in Berkely-Street, are open, not only to the medical officers of the army, but to the profession at large.

ROYAL INSTITUTION,

Friday, May 21, 1830.

B. B. CABELL, ESQ. F.S.A. VICE-PRESIDENT, IN THE CHAIR.

New Musical Instruments.

MR. FARADAY exhibited to the meeting several new musical instruments which have lately been constructed, on the principle of the *Æolina*, with metallic springs, such as were explained here last season in their simpler states. The "*mut-harmonicon*," on its introduction about three years since from Germany, was believed to be an entirely original discovery; but lately it has been ascertained that the Chinese organ, an instrument which that extraordinary people have possessed time immemorial, contains a similar mechanism; although they were in the habit of taking the vibrating springs out of those they sold to strangers, so that their construction remained long concealed.

The instruments are still in a rudimentary state, but they possess a peculiar fulness and sweetness of tone which promise much when more advanced towards perfection. The *Symphonium* is even now an admirable instrument, and the *Æolian* organ, although harsh in its higher, is very excellent in its lower notes.

Lithotritic Instruments.

On the library table were the lithotritic instruments which some years ago Mr. Lukin, the American, submitted to the inspection of several surgeons, both in this country and on the continent. They are certainly very inferior to the improved apparatuses of Civiale and Heurteloup, which were shewn here last Friday; but if, as was stated, they were the first invented*, they shew great ingenuity, and claim for their constructor much credit. In them, in fact, seem to be included the chief of the principles which in the others have been perfected; for the canula is *straight*; it contains a four-branched forceps, through the centre of which either a trephine-drill or chisel is made to act upon the stone. The forceps in this apparatus terminate in watch-spring loops, for the retention of the stone; and the two-branched forceps are only fitted to *extract* small fragments, being far too weak to crush a calculus; as will the brise-coque or the brise-pierre. They are ingenious, but we think not useful instruments.

HOSPITAL REPORTS†.

ST. THOMAS'S HOSPITAL.

Swelling above Knee-Joint.

HENRY DUNNING, aged 38, admitted under the care of Mr. Travers, on Thursday, April 29. He states, that about twelve months ago he was engaged in an occupation which required him to kneel, and in which position he remained for the greater part of two days, the weather at the time being very wet. On the third day after this a swelling made its appearance, a little above the knee joint, attended with a good deal of pain; he was now required to give up his work, and could only walk with the assistance of a crutch or stick. A fortnight after he applied to a medical man, who gave him a liniment, which inflamed the skin, and made the knee more painful; this was changed for strapping and plaisters, but without deriving any benefit—

the knee continued to get larger daily. Finding this mode of treatment unsuccessful, blisters were next had recourse to, and thirteen were applied in succession, which rather aggravated than alleviated the complaint. Soon after the blistered surface was healed, the swelling gradually became less, and he was able to go about his usual employment—that of a husbandman. He continued to work for upwards of two months, but at length found himself incapacitated. Nothing worthy of remark occurred from this time, until about seven weeks ago, when the knee began to increase in size, attended with considerable pain; a poultice was applied, and in a few days the swelling burst on the upper and inner part, and discharged upwards of a quart of thin yellowish matter. For several weeks previously he had been unable to procure any rest; but after the evacuation of the matter he found a good deal of relief.

Poultices have been kept applied up to the present time, and several other openings have formed spontaneously, through which fetid pus escapes. A probe can be passed into each of these apertures to some extent, but they do not appear to communicate with the joint. The swelling is of enormous size, the largest diameter being some distance above the articulation. He can flex and extend the limb without pain, and also walk without much inconvenience. When the knee is bent, a discharge of matter takes place from the wounds, in a small, but continuous stream. The joint appears enlarged from a collection of fluid, and the patella pushed out of its natural position, and is easily moveable. The patient is of a tall spare habit, with a sallow complexion; the abdomen is tense; the bowels much relaxed; tongue white at the sides, red down the centre and at the tip; pulse 81, weak and irregular.

May 5th.—A poultice has been kept applied to the knee, and he has taken the chalk mixture with opium, but without lessening the diarrhoea; a good deal of fetid matter escapes through the wounds, with dead portions of cellular membrane. He complains of great thirst. Tongue and skin dry; pulse 89, very weak; no appetite. The knee is not altered in appearance since admission.

7th.—A crucial incision was made into the swelling this morning at ten o'clock, each cut being about four inches in length, and half an inch deep. At the time he appeared very anxious. Nothing escaped but a very small quantity of blood. A cold poultice was applied, and he lost about four ounces more blood, which flowed into the poultice. About half an hour after the operation he was seized with pain in the stomach, and vomiting; also excessive tenderness on pressure at the scrobiculus cordis, and great distension of the abdomen; pulse scarcely per-

* Is the writer aware of the claims of Mr. El-derton—as advanced in the preceding volume of the Gazette?

† The notice in our last respecting the boy on whom Mr. B. Cooper operated for stone on the 11th, was premature;—the child is now doing well, but it was only on the 24th that the urine for the first time passed by the catheter.

ceptible. A small quantity of warm brandy and water was administered by the sister, which remained on his stomach only a few minutes. He was again visited by the dresser about eleven, when the symptoms continuing the same, half a drachm of tincture of opium was given in a little water; this was rejected in about a quarter of an hour. Hot fomentations were applied to the epigastric region. At one p.m. we saw him; his pulse was then imperceptible; the least pressure, even the weight of the hand, at the scrobiculis cordis, appeared to induce the most acute suffering; his respiration was difficult, with restlessness and anxiety; and he expressed his conviction that he should die, unless speedily relieved.

About two he was visited by Mr. Whitfield; more brandy and water was given, which raised the pulse, but did not relieve the symptoms. This dose was not rejected. He continued to get more restless until about three o'clock, when he wished to get out of bed to go to the water-closet; he was not allowed to do this, but a bed-pan was procured, and he passed a watery motion; soon after, on raising himself up in bed, he instantly expired.

Inspectio Cadaveris.—On cutting through the integuments over the swelling, the first morbid appearance which presented itself was the cellular membrane in a sloughy state, equal in extent to the diseased skin; next to this the muscles, viz. the rectus and vasti, were found completely altered in their structure at this part, and converted into an uneven dense mass of a yellowish colour. Growing from the periosteum there was another, about three inches in diameter, of a flattened shape, and of similar appearance in texture; the bone beneath being scabrous. In the joint there was a considerable quantity of clear fluid. No communication was detected between this part and the swelling above. On the inner surface of the synovial membrane there was an immense number of small tubercles, which appeared of a fatty nature, and about the size of pepper-corns. Small but deep ulcerations existed on the articulating surface of the femur, seemingly of old standing. The condyles of the femur enlarged; the crucial ligaments and interarticular cartilages appeared healthy.

Abdomen.—Liver more than twice its natural size, and of a nutmeg colour—easily broken up underneath the fingers; spleen five or six times the natural size, and very much indurated. The stomach was also larger than usual, and its mucous coat softened; the cardiac extremity was of a dark red colour, but this was probably caused by a transudation from the spleen. Patches of red on the mucous surface of the colon, but no ulceration. The kidneys were much softer than natural; some of the pelvic

glands on the right side about the brim enlarged. Testes enlarged slightly, and hardened. The lungs were healthy. Heart and brain softer than natural.

Scars were observed here and there upon the body, which seemed to be the relics of scrofulous abscesses.

WESTMINSTER HOSPITAL.

Painful Affection of the Left Arm from External Injury—Cured.

SELINA CLIFFORD, æt. 16, admitted April 22, 1829, under Mr. White. This is rather a remarkable case of painful nervous affection caused by blows received on the arm.

Fourteen months ago, a little boy, in a fit of passion, struck her two or three times with a piece of iron, she thinks half a pound in weight, which was attached to a string in his hand. She had a baby in her arms, and in putting up her left arm to save it, received the blows on the outside of the fore arm, from the wrist to the elbow. Discoloured lumps came where the blows had been received, and on applying to a surgeon she had forty leeches applied, and from one to two dozen every day for a fortnight; her arm being much swelled, as high as the shoulder, and exceedingly painful.

She then had poultices applied for three months without any benefit. The injury seems to have been very severe, for she says her fingers were much swelled, and as "black as ink;" for nearly three months they remained discoloured. Her arm always swelled much at night; and about four months after the accident, it appears three sloughs came away where the blows had been inflicted.

After these had healed, her arm still remaining painful in the extreme, six blisters were applied one after the other: for three months her arm was much swelled, and became œdematous. Mr. White freely scarified it, and a great deal of fluid was discharged.

Her arm was then bound up, and occasionally fomented, for about two months, when she was admitted into the hospital. There was an eruption over the whole arm; the slightest movement of the limb gave her pain, and the lightest touch was like an elastic shock through her whole frame, more particularly in passing the finger on the ulna at the elbow, and along the course of the radius.

On being admitted, she had her arm fomented, for nearly two months, with an infusion of hemlock, and she took various preparations of iron. During this time, her arm became better than it had ever been before. She was, however, ordered to discon-

tinue the fomentation, and try to move her arm about, when it soon became as painful as ever.

She has since taken the quinine in full doses, without any evident effect.

She menstruated, for the first time, five months ago, and has since been regular. She was electrified about a month ago, and though she said her arm was more painful afterwards, it seemed to be less so below, though more on the upper surface.

Aug. 27th.—She was transferred yesterday to Mr. Guthrie, who ordered her

Tinct. Ferri. Ammon. ʒj.

Infus. Calumbæ, ʒiiss. bis in die sumend; and her arm bandaged and put in splints, from the finger-ends to the shoulder.

Aug. 29th.—She has had the following ointment applied, and strapping over it from the fingers to the shoulder, and splints the whole length, so as to prevent all motion.

R Ung. Hyd. fort. ʒj.

Camphoræ, ʒj. ft. Ung.

September 5th.—She continues much the same.

R Ol. Terebinth. ʒj. ter in die sumend.

Oct. 3d.—She has omitted the oleum terebinthinæ, on account of the irritation it excited in the urinary organs. The pain is less in the forearm, but increased higher up. She is ordered four leeches every night, to be applied to the lower cervical vertebrae.

10th.—She complains of much pain down the whole of her arm, when the lower part of the back of the neck is touched.

14th.—The pain in the arm is much worse.

21st.—The moxa has been applied this morning in five places, from the spine of the neck towards the shoulder.

25th.—Moxa repeated. Since the application of the moxa the leeches have been discontinued.

28th.—The moxa was applied again today; the leeches were again applied last night, and ordered to be regularly continued. The under surface of the arm and fingers is less painful, but the upper surface is much the same.

Nov. 4.—She can move the fingers more freely, and bear pressure on the arm better; but the shoulder is very painful.

10th.—The pain is less both in the shoulder and arm.

14th.—Improving; the arm has been again strapped up.

Dec. 29th.—The application of the leeches and moxa has been continued, and she has improved very gradually. She suffers at present from severe cough and pain in the chest.

Jan. 14, 1830.—She has had a very severe attack of pleuritis—frequently relapsing when apparently recovering. She has had the usual

remedies, blisters, leeches, &c. and is now quite out of danger.

Feb. 14.—On examining the arm, all tenderness on pressure has entirely left her; she is perfectly free from pain, and can make use of her arm without inconvenience.

16th.—Dismissed quite well.

GLASGOW INFIRMARY.

Injuries of the Head.

CASE I.—James Armour, aged 27, a quarrier—admitted 8th May. The accident had happened a week previously, and was occasioned by a quantity of earth falling upon him. He remained insensible two hours, during which considerable hæmorrhage is said to have taken place from the right ear. On recovering, he felt acute pain on the right side of the head, for which he was twice bled with marked relief. On admission he had little or no uneasiness, and complained chiefly of giddiness when he attempted to raise his head from the pillow. He was perfectly blind of the left eye, the pupil of which, however, contracted freely on exposure to light. The sense of hearing of the right ear was much impaired. His mouth was slightly drawn to the left side, which deformity increased greatly when he spoke. The pulse was about 60, the skin cool, and in other respects he was under no fever. The bowels were freely opened, and, on the following day, a large blister was applied to the head. On the 13th, four days after admission, there was an accession of feverish symptoms, with return of headache, and deep-seated pain under the right ear, the hearing of which was completely gone. The pulse was full, and had risen to 90. He was bled from the arm, and the blistered surface was ordered to be dressed with savine ointment. On the 14th, the pain in the head and ear had all but gone, and in every other respect he felt greatly better. The features were much less distorted, and he had recovered in part the hearing of the right ear. The pulse had fallen to 70. The blister was repeated to the head, and he was ordered gr. ii. calomel three times a day. In the course of a week his mouth became affected, and the medicine was therefore omitted. He continued daily to improve, and was dismissed well on the 8th June, having been a patient in the hospital exactly a month. At this date the features did not appear to be at all distorted, except when he laughed or attempted to smile. He did not recover the sight of the right eye.

There was a combination of symptoms in this case. It was evidently one of concussion with partial compression. The insensi-

bility in the first instance, and the gradual recovery afterwards, are characteristic of the former; while the amaurotic state of the left eye, and the palsy of the right side of the face, evince the latter. These symptoms, no doubt, could be accounted for on the ground of its being a case of pure concussion. In what is termed concussion of the spine, for example, we often witness more or less palsy of the bladder and lower limbs to succeed. Exactly the same may be said to take place in similar injuries of the head; nevertheless, I am disposed to attribute these effects in a great measure, if not altogether, to compression. The hæmorrhage which occurred immediately after the accident shews, of course, that there had been rupture of a blood-vessel, and consequent effusion of blood. This, in every probability, took place in some part of the tractus opticus of the right side, or farther back at the origin of the nerve. In this way, too, can be explained the dulness of hearing, and the loss of muscular power of the right side of the face.

This person was not admitted till after the eighth day, by which time the inflammatory stage subsequent to the accident had subsided under the usual means. The principle observed in the treatment was to excite absorption, if the symptoms depended on effusion; or, supposing these to be the consequence of concussion, to rouse the tone of the nerves. Both ends, probably, were accomplished by the measures had recourse to; namely, counter-irritation, and the exhibition of mercury.

On the fourth day from admission, there was a return of feverish symptoms, with pain in the situation of the ear, which readily yielded to a full bleeding. This perhaps depended on an inflammatory state of the brain, excited by the effused blood. In cases of effusion into the substance or on the surface of the brain, we often meet with accessions of inflammation occurring in the progress of its absorption. In this respect, the presence of the fluid seems to act merely as a cause of irritation, and may therefore be compared in its operation to that of an exostosis, or any other tumor, in producing fits of apoplexy, &c.

One other circumstance in this case ra-

ther uncommon, may be mentioned, viz. that the motions of the iris of the blind eye remained perfectly free. From this it is evident that the mobility or immobility of the iris is by no means an index of the sensibility of the retina at all to be depended on. This is owing to the iris being supplied by the ciliary nerves, which proceed from the lenticular ganglion. I have frequently met with cases of amaurosis with active pupils, and *vice versa*,—an immoveable state of the pupil with perfect sensibility of the retina.

CASE II.—James Gorman, aged 30, admitted 4th June, in a state of insensibility, having on the preceding day, while in a state of intoxication, leapt from the roof of a one-story house, and pitched upon his head. The only external injuries visible were an abrasion of the left cheek, and a dislocation of the first phalanx of the left thumb backwards on its metacarpal bone. He is said to have vomited freely after the accident. When placed in bed, he lay in an insensible or rather semi-comatose condition, returning no answer when loudly questioned. He moaned frequently, and seemed acutely sensible to pain, as evinced by his restlessness in drawing up and then throwing out his limbs when firmly pinched. The pulse was 120, sharp, the respiration slow and deep-drawn, the skin hot and dry. Immediately on admission the dislocation was reduced, during which he struggled much in violently resisting attempts at extension. Twenty ounces of blood were then taken from the arm, 16 leeches applied to the head, to be succeeded by cold application; and he was ordered a purge of calomel with infusion of senna and salts. The bleeding from the arm was repeated on the 5th. On the 6th he was more composed. The pulse was down to 90, and soft. He put out his tongue when requested. The pupils, particularly the right, were dilated. On the 8th he was in every respect perfectly intelligent, though he still complained of slight headache. The pulse had fallen to 70; the tongue was clean and moist. On the 9th he appeared worse, having passed a very restless night. He had a vacant expression of countenance, with stupidity in answering questions: a blister was in consequence applied to the head. He had a more restless night, and was so very delirious as to require the straitjacket: the pulse, however, was no way excited, the skin cool, and he had no thirst. The blistered surface was dressed with savine ointment, and he was ordered gr. ii. calomel every third hour. He was kept on low diet. The mercury was continued till the mouth became smartly affected. He daily got better, and was dismissed well on the 1st July.

This man was re-admitted a fortnight afterwards, complaining of vertigo, of double vision on walking, and of pain occasionally shooting through the head. He was cupped on the nape of the neck, a blister was applied to the head, and he was ordered to use a mercury pill three times a day. On the 22d, five days after admission, the mouth is reported to be affected, when all the symptoms were greatly relieved. On the 29th the medicine was recommenced, and a caustic issue burnt in the nape of the neck. So soon as the mercury again took effect, and violent ptyalism was induced, the symptoms wholly disappeared. He was dismissed cured on the 10th August.

He was again admitted on the 23d, labouring under nearly the same symptoms as formerly, but with little or no pain of the head. The issue, which had nearly healed up, was opened, and the mercury repeated, with the use of a strong stimulating liniment for rubbing the surface of the head. On the medicine fairly appearing in the mouth, the unfavourable symptoms began to wear off. The mercury was repeated, and he finally left the hospital cured, 15th Sept.*

This man was admitted on the day subsequent to the accident. With the exception of slight abrasion of the cheek, there was no visible mark of injury elsewhere on the face or skull. Nevertheless, it appeared at the time, and as its issue proved, a very severe instance of concussion, complicated most probably with slight extravasation. The primary effects had worn off, and the stage of re-action had commenced many hours before he was brought to the hospital. In cases of this kind, an interval of sense usually takes place between the injury and re-action. In this case, however, there was no such interval, and consequently the symptoms of concussion were gradually and imperceptibly converted into those of inflammation. He did not recover intelligence before the third day. The treatment was very simple. The man had suffered a severe mechanical shock, to which inflammation, as a necessary consequence, had succeeded. The chief indication, then, was to subdue arterial action. This was effected by bloodletting in sufficient quantities to control the force of the circulation, the advantages of which were strikingly apparent. Although rather a tedious case, it was otherwise very inte-

resting. The frequent return of vertigo, double vision, &c. proves to me that it was, in every likelihood, complicated from the commencement with partial laceration of the brain, and slight extravasation of blood; or that perhaps effusion of serous fluid had happened after the cessation of the inflammation. I should have imagined it more likely to have been caused by the first. One or other of these circumstances, however, sufficiently explains the loss of memory, giddiness, double vision, &c. We often find similar effects to supervene on the cure of phrenitis, or in cases of fever where there has been a great flow of blood to the head, and more particularly in injuries of the head with decided extravasation of blood.

For the removal of these symptoms, the treatment consisted in obviating, in the first instance, the chance of the recurrence of inflammation, and afterwards in favouring absorption by counter-irritation. The former was accomplished by cupping and the use of purgatives; and the latter by the repeated application of blisters, and the formation of a caustic issue. After a sufficient trial, these were found to be perfectly ineffectual. Mercury, as an ulterior measure, was therefore had recourse to, and used freely and repeatedly with the best effect.

As soon as the mouth got fairly under the influence of the medicine, the unfavourable symptoms uniformly began to subside. Their frequent recurrence convinces me that the brain perhaps may have been slightly lacerated, giving rise to partial effusion of blood, either at the time of the accident, or at a period subsequently to it. Instances of secondary hæmorrhage are certainly rare, though several are on record. The same line of treatment is applicable to both cases.—*Dr. Auchincloss, in the Glasgow Medical Journal.*

NOTICES.

A correspondent is anxious to know when the promised continuation of Mr. Tyrrell's edition of Sir A. Cooper's Lectures may be expected?

The last page of the article in answer to our notice of Dr. Corrigan's paper has been mislaid. Can the author supply us with the conclusion?

* This person called on me early in February, on his return from Ireland, where he had resided since leaving the hospital. During that period he had enjoyed good health.

LECTURES ON SURGERY,

Delivered at St. Bartholomew's Hospital,

BY WILLIAM LAWRENCE, F.R.S.

LECTURE XLVIII.

Recapitulation — Ununited Fracture — Compound Fracture—General Treatment—Question of Amputation.

I SPOKE to you, gentlemen, in my last lecture, of the different modifications of bandages that are applied to broken limbs. The eighteen-tailed bandage is the one [pointing to it] which is placed before you: it is so named because on each side there are nine of these small ends, which are called tails. The bandage is made of three broad pieces of linen, which are sewed to a straight piece transversely; the second overlaps the first by about one-half, and the third piece overlaps the middle one in a similar way; and each of these three pieces being divided at either end into three smaller parts, there are thus in the whole eighteen ends or tails. Now each of the three portions of linen which is thus divided must be long enough to encircle the limb once and a half at all events. Beginning the application of the bandage from below, the successive parts overlap in order, so as to enable you to exert a direct and regular pressure in the circular direction of the limb.

The bandage more commonly used now is very similar, but is made of pieces separate in their whole length, and indefinite in number; these are sown together on a straight piece in the same way. This is the many-tailed bandage, the parts of which it consists not being limited to any particular number.

The bandage of Scultetus consists merely of a certain number of these separate transverse pieces not united together.

I mentioned to you the different materials of which splints are composed. This is the ordinary form of a wooden splint for the leg [presenting it]: we find it necessary to employ two of this sort—one adapted to the external, and one to the internal side of the leg. This is a similar kind of splint [exhibiting it], made of japanned iron. In using either of these, you will find it necessary to be on your guard not to have the splint too much hollowed out; for when the limb is swelled, as it commonly is, in consequence of the violent injury which it receives in a fracture, it becomes of considerable width, and more or less flat on the surface, so that if you put on a splint as much hollowed as the one I now show you, the edge will press injuriously and painfully upon the surface of the limb. It must be a very small limb that we could place in the concavity of this splint, therefore it is an ill made one in that respect. It should be nearly a level surface, though a little excavated in the middle, in order to support the limb pleasantly, and avoid pressure of the edges upon the soft parts of the limb. These splints [shewing them] are called line splints—they are made of pieces of split deal, connected by leather glued on the surface. They are convenient on a variety of occasions—sometimes to confine a limb temporarily till a more suitable apparatus can be permanently applied—sometimes, where we want a small splint to apply to any particular part, we can cut them; and inasmuch as they are flexible in the transverse direction, they accommodate themselves to the form of the limb.

When a limb has experienced considerable bruising by the same injury which has caused the fracture of the bone—when, consequently, blood has been effused into the cellular texture, and the limb is considerably swollen—you may anticipate the occurrence of inflammation, just as you would do from a similar injury of the soft parts not connected with the fracture. If you had an injury of that kind without fracture of the bone,

you would not think of binding the limb up firmly with bandages; and, *a fortiori*, if you applied wooden or iron machinery of this kind to it, so as to embrace it tightly, you would of course think that mode of proceeding likely to aggravate the inflammation which the injury of the limb may be expected to produce;—now the circumstance of a bone being broken does not render it at all more proper for you to adopt that course of proceeding in such an accident.

In the first place, you should put out of consideration the circumstance of the fracture, and treat the case as you would do a similar injury of the soft parts not connected with fracture. You should endeavour to prevent the occurrence of the inflammation which the injury is likely to produce—you should endeavour to reduce the swelling which the bruise and ecchymosis have occasioned; and when you have removed all risk of that kind, then you may proceed to bandage the limb, and to apply the splints proper for the fracture. In such a case, then, in the first instance you would lay the limb in the position most agreeable to the patient's feelings, and generally that is the half bent state, such as patients usually throw the limbs into when they sleep: you lay the limb in this way on a soft pillow, and then you adopt either the local or general means that are necessary to reduce the swelling, and limit the extent of the inflammation; such as leeches to the part, cold washes, and other means contributing to the same purpose. You may find it necessary to pursue this treatment for some days before you think it expedient to apply the dressing which is more particularly proper for fracture; and you will find it advantageous to reduce completely the inflammation and swelling of the limb before you proceed to confine it in the way which the fracture requires.

The same reasoning applies if the limb should swell after you have put on your fracture apparatus. The patient sometimes feels the apparatus painful—it makes the limb uneasy, particularly after it has been a few hours confined; and you may occasionally find it expedient to undo the apparatus during the day-time, to leave the limb on a broad splint, apply a cold wash, and other means necessary to reduce the inflammation, and then slightly to confine it during the night, in order to prevent the patient being troubled with the spasmodic twitches that are likely to occur if the limb is left entirely unconfined.

With respect to that particular circumstance which is so often a considerable annoyance to the patient—spasm of the muscles of the limb, twitches by which the edges of the bone grate against each other—we find it difficult in some cases altogether to prevent them. The more completely we keep off the occurrence of inflammation, the

less likelihood there is that the patient will be troubled in this way. After the inflammation is removed, the more exactly we adjust the fracture—the more immovable the fragments are kept—the less probability there is of the occurrence of spasm. I believe you seldom find much advantage from the exhibition of any means that are supposed to have a direct influence in alleviating spasm—opium, or any other thing of that kind.

Frequently the skin is very seriously bruised in cases of fracture. Ecchymosis takes place in the cutaneous texture, rendering the external surface of a deep livid red, and the injury to the skin is often so considerable that the minute vessels of the surface pour out a serous fluid, and vesication of the cuticle occurs on the bruised part. These vesicles often contain a turbid and dark, sometimes a livid or reddish fluid; and it happens occasionally that such vesicles, combined with the deep red or livid appearance of the bruised parts, lead persons to apprehend that mortification has occurred, or is about to take place. The appearances, indeed, are sometimes deceptive; you will nevertheless find, in cases of simple fracture, however extensive this livid and dark red appearance of the skin may be, however considerable the vesications that may occur, that they are simply the consequences of bruises of the skin, and do not portend any danger of mortification. All you have to do is to prick the vesications, let out the fluid, and lay on the surface of the part simple dressing, such as spermaceti ointment on lint; and you find that the integument does not lose its vitality, but recovers very well.

Ununited Fracture.

After a fractured limb has been kept in a suitable apparatus for the length of time which is ordinarily found sufficient for the union of the bone, we sometimes discover, on removing the apparatus, that the bone has not united. Occasionally we find the fracture quite loose, the limb moveable in the situation where the fracture has taken place, and sometimes such a want of union continues for weeks, and even for months, nay, often at the expiration of a year or more, the fracture will not be consolidated;—it is then called a case of *ununited fracture*. This, of course, is a very unpleasant occurrence both to the surgeon and to the patient. The limb is rendered useless, or nearly so—that is, it bends in the situation of the fracture, just as a joint. By the exertion of the muscles the bones rub against each other; and when such facility of movement occurs, it leads to the supposition of a joint being actually formed in the situation where the fracture has taken place; indeed, in coming to examine these cases, in some instances

there is a kind of smooth surface of bone produced—there is a kind of condensed investment surrounding it—something like an imperfectly formed joint. More commonly, however, the bones are found connected together by a kind of ligamentous texture. It is important to ascertain, in this case, whether the want of union arises from any thing particular in the fracture itself, or from any peculiarity in the constitution of the individual; or whether it is referable to some part of the treatment which ought to be adopted for the consolidation of the bone either having been neglected or having been inefficiently applied. The question will therefore be, whether the occurrence is owing to any thing that belongs to the nature of the fracture, or to something peculiar in the constitution of the patient, or to something inefficient in the treatment.

I apprehend, if we take all the cases of want of union, we shall find more reason for concluding that the deficiency arises from the latter cause than from either of the two former. Mr. Amesbury, who has paid particular attention to the treatment of fractures, and who has published some observations on the subject which are very well worthy your perusal, seems to have had a great number of cases brought under his observation; for, in a work published some time ago—"Observations on Fractures,"—he has collected a great many such instances, and has related his own experience in ununited fractures; and from this experience he expresses very decidedly his opinion, that it is to the inefficient means adopted for bringing into, and retaining in proper apposition, the broken ends of bones, that the defect of union is generally to be ascribed. Consequently the treatment that we should follow, to avoid the possibility of this occurrence, consists rather in carefully maintaining the fracture in apposition in the first instance, than in any other course of proceeding. Mr. Amesbury says, that in a great proportion of the cases which came under his care, when a properly contrived apparatus was applied, and the broken ends of the bone were brought into accurate contact and retained firmly in apposition, the fractures united within a moderate length of time. But inasmuch as it may be supposed that, in consequence of the length of time that may have elapsed since the receipt of the injury, there is some defect in the increased action which seems necessary to the consolidation of the fracture, he recommends, not merely the applying of an apparatus for retaining the bones in contact, but the combination with that of the use of pressure upon the situation of the fracture, in order to excite increased action. This may be accomplished by using particular kinds of pads, so as to press upon the part, or by other contrivances of a mechanical nature connected with the apparatus

you employ; the object being simply to exert such a degree of pressure as shall excite a certain degree of pain in the part, that lasts for a few days—something like rheumatic pain. When the case has been conducted in the way I have already mentioned to you, Mr. Amesbury has found that the ununited fractures have united readily enough. He observes—what I think accords with my own experience on this subject—that individuals in whom defect of union is thus seen, are generally persons of healthy constitution; those in whom we cannot observe any evidence of defect in those natural powers, from the exertion of which restoration is to be expected.

It is important to ascertain the point that I have now mentioned to you, because, if the union can be accomplished by the simple means that I have stated, we shall save our patient from the necessity of undergoing other kinds of treatment, which are both painful and dangerous; for, in cases of these ununited fractures, proceedings have been adopted, with a view to produce union, which at all events have generally required a long course of confinement, and in some instances have produced much local disturbance in the limb, and in fact have proved ultimately fatal to the patient. Sometimes incisions have been made in the situation of the fracture—the fractured ends have been exposed in a wound, and actually sawn off. This I need not observe to you is a serious proceeding; indeed, in the middle of a fleshy limb, as the thigh for example, it must be a very difficult thing to accomplish. You inflict an extensive wound—one which is very likely to be followed by considerable inflammation and other dangerous consequences; and in many of the instances in which this process has been undergone, the patient has been left in a worse state after the operation than he was in before.

Another mode of proceeding in these ununited fractures, has been that of passing a seton between the broken ends of the bone, and leaving it there, in order to excite in the ends of the bones and the neighbouring soft parts that action which is supposed to be inefficient. After a certain degree of inflammation has been excited by the seton, it is then to be withdrawn, trusting the union to natural powers. I believe it may be said that there are some two or three instances recorded in which, after some weeks or months of confinement, with a good deal of pain and danger, the union has been effected in this way; but in other cases the introduction of the seton has failed. Sometimes blisters have been applied externally, and then rubbing the broken ends of the bone together has been tried, in order to excite the necessary degree of action where it had not previously taken place: these, at all events, are not dangerous proceedings.

Compound Fractures.

I proceed next to speak to you of the management of *compound fractures*: the observations that have been hitherto made are applicable to the cases of simple fracture. In compound fracture, the soft parts may be divided by the same violence which breaks the bone—as in the case of a wheel passing over a limb. A contused and lacerated wound of the soft parts is made by the wheel, at the same time that it causes the fracture, and in such a case you have often a large external opening. More commonly the bone is broken first, and then the fractured end (particularly if the fracture be oblique, so that a part of the bone has a sharp extremity, and therefore easily slips off the corresponding surface) is forced through the soft parts, in consequence of the exertion which the patient makes with the limb after the fracture has occurred. The patient rises perhaps, and attempts to walk or stand upon the leg, and thus the end of the bone is forced through the skin. When an accident of this kind occurs to a person who is intoxicated, not being aware of what has happened, he makes violent efforts to rise, and thus the end of the bone is not only forced through the soft parts, but through the dress—through the stocking—and sometimes it has been forced through the patient's boot. In these cases, where the division of the soft parts is secondary, the external wound is usually small—sometimes a mere puncture, produced by the sharp edge of the bone—while the internal injury in such a case is perhaps just as extensive as in the former instance.

The degree of injury is extremely various in cases of compound fracture. In the most serious cases it becomes a question whether the loss of the limb may not be necessary, in order to prevent the risk which would otherwise accrue to the life of the patient? It is difficult to lay down precise rules in order to determine this point. Each case presents something peculiar to itself, and it will be necessary for the judgment of the practitioner to be exercised, after a careful consideration of the peculiarity of each individual instance. We can only speak in a general way as to the principles that should guide us in determining this important question. We must attend to the degree of injury which the parts have experienced, and also to the greater or less importance of the parts involved. For instance—we must see whether the joints are at all injured—whether it is probable that any considerable blood-vessel, or any large artery, be implicated. The age and constitution of the patient must be taken into consideration; and it is also sometimes a question of importance to ascertain whether the patient will have such professional care and such comforts as his situation requires.

Comminuted fracture of the bone, with the soft parts extensively torn and mangled, in consequence of the limb having been entangled in machinery, for instance, is a case respecting which we can be under no doubt at all: amputation is necessary under such circumstances. You sometimes find a limb half or three-parts torn off by an accident of this kind, where the fracture of the bone is by no means the most important part of the injury: in such a case it is obviously necessary to amputate. Cases of comminuted fracture, with serious bruising and excessive laceration of the soft parts, where the bone is extensively exposed and denuded, with the soft parts separated from it, more especially if the fracture be in the neighbourhood of a joint, with a great probability that it extends into it, and with the probability also of the main artery or arteries being injured—that kind of case is one in which amputation may be proper if it occur in an old person, in a person of enfeebled constitution, or if it take place in an hospital or any crowded situation, where the process of recovery generally proceeds comparatively less favourably. But the same kind of injury may not be thought to require amputation if it occur in a young subject, one of vigorous constitution, in an individual who is situated in pure and wholesome air—as in the country. We must be on our guard against hastily condemning a limb in a case of this kind; for the resources of nature are so great, that sometimes we see injuries repaired without any unfavourable occurrence, though we may have anticipated that the loss of the limb would prove inevitable.

I remember the case of a lad who was brought into this hospital, and came under my care, with a dreadful compound fracture of the leg, produced by a cart-wheel going over it. The accident had so occurred that the wheel had rested upon the leg, and, in addition to very great laceration, there was an external wound of some inches in length, leading down to the ankle. About four inches of the tibia was completely denuded and the soft parts almost detached, the bones projecting, and the fracture as well as the wound extended close to the ankle-joint. I considered this to be a case in which amputation would be proper, and I represented my opinion of the necessity of the measure to the patient, but he seemed to have made his mind up upon that subject,—he would not part with the limb; and the representations that were made to him of the probable loss of life had no effect in altering his determination—he would not have it removed. The limb was laid on a broad splint, on the opposite side to that on which the accident occurred—namely, on the inner side of the leg. Means were adopted for accomplishing the cure as well as we could and preventing the occurrence of inflammation, and the

case got well really without a single unfavourable symptom taking place. In about a dozen or fourteen weeks the wound, which was extensive, had consolidated, the fracture united, no exfoliation of bone occurred, and the lad had a good strong limb.

You are not to consider the size of the external wound as a criterion of the degree of injury; it is the violence which the bone has experienced, the contusion and laceration of the soft parts immediately around it, and the injury of the joints or large arteries, which constitute the source of danger in these cases. *Ceteris paribus*, I think it is desirable, in a compound fracture, to have a large aperture, because such free external wound affords a ready exit to matter—large collections of which sometimes take place;—in many instances of that kind you see that the case does better than where there is only a minute external opening of the skin.

The reason of amputating in a case of compound fracture, is the danger that would accrue to the life of the patient from the consequences of the injury if the limb were not removed. In the very serious cases of this kind which sometimes occur, traumatic gangrene, mortification of the limb generally, may be expected to come on; violent inflammation of the whole limb, with a corresponding febrile disturbance of the system, which may run to such a height as to endanger life. Then there is more remote danger from repeated suppurations, and from the exhaustion of the powers which take place when they get into the chronic stage—when there is a copious thin discharge, with hectic fever. Another consideration which influences us in these cases, is the very imperfect and sometimes useless state of the limb, after the patient may be said to have recovered from the injury. The injury which the soft parts and bone have sustained are so considerable, and repeated inflammation and suppuration have produced such thickening and stiffness of the muscles, tendons, and other parts, that the patient perhaps recovers with a limb in a condition not at all useful to him, but, in point of fact, rather burthensome than otherwise; and that too after many months, nay sometimes after years, of suffering. These are the considerations which induce us, under certain circumstances, to regard it as expedient to amputate the limb rather than to attempt its preservation.

The same question occurs in these cases as in the instance of serious injuries to limbs from gun-shot wounds, respecting the time at which amputation may be most advantageously practised; for in cases of compound fracture, as in those instances, amputation may be either performed immediately after the occurrence of the accident, or we may defer it, in order to allow of the subsidence of the inflammation and fever which

come on soon after the accident. I had occasion to consider fully, when I spoke to you of gun-shot wounds, the question that I am now adverting to; and I stated then, that there is no doubt whatever of its being by far the most safe, and consequently the most eligible practice, to perform amputation immediately—that is, within twelve, or say at most within twenty-four hours, from the occurrence of the injury; and all the considerations which lead to that inference in cases of gun-shot wounds are equally applicable to cases of compound fracture that require amputation—I therefore need not go over the ground again.

When we treat a compound fracture with a view of repairing the injury and restoring the limb to a useful state, we generally, but not invariably, attempt to produce union of the external wound: we bring the parts together and retain the edges of the wound in contact, in the hope that they may become united, and thus that the compound fracture may be converted into a simple one. Now we do not very often succeed in this, because the wound of the soft parts is not of a kind favourable to the occurrence of adhesion; it is a lacerated and contused wound, and wounds of that kind do not readily unite by adhesion. We may make the attempt, however, for there can be no harm in doing that. We may either draw the edges of the wound together with short pieces of sticking plaster, or by the application to the wound of lint dipped in the blood that flows from it. This dries, and forms a kind of external crust upon the surface of the wound, under which it may unite; and if we can succeed in producing this closure of the external wound, we know that the case will go on very much as if it were merely a simple fracture.

It is necessary in compound as in simple fracture, to bring the displaced ends of the bone into their proper position—to place them in contact, and to maintain them so. But the injury which the soft parts have experienced is one of the circumstances that requires our particular and early attention. In almost all instances, these soft parts have been considerably contused and torn, and we may naturally expect that, in consequence of such injury, inflammation, suppuration, and fever will occur; renewed inflammation and suppuration—repeated formations of matter. And you will recollect that inflammation here occurs in the cellular texture, in the very centre of the limb; you will remember how easily inflammation, when it takes place in the cellular substance, runs along that texture so as to extend to the whole length of the limb in a short time—as in the case of phlegmonous erysipelas. When, therefore, the internal cellular structure is the seat of inflammation, and when the progress of matter to the surface is im-

peded by muscles, tendons, and fascia, which are seated externally to it, the extension of suppuration in the intervals of the muscles throughout the whole length of the limb, is a very formidable occurrence. These are consequences of fracture which we must endeavour as much as possible to avert or limit; and hence the question occurs, what is the course most likely to accomplish this purpose? You find it necessary here, as I mentioned in the case of simple fracture, with contusion or laceration, to put out of consideration for a time the fracture of the bone, and to adopt the means that are necessary to prevent the occurrence of inflammation in the soft parts. You will certainly not expect to prevent this occurrence of inflammation by tight bandages and the application of hard wooden or metallic splints to the limb; on the contrary, you would think such a mode of treatment very well calculated to increase the mischief. You must adopt, in such cases, active antiphlogistic treatment, just as if you had the same injury in the soft parts without the fracture. In young and strong patients of full habit, where there is such injury, you must bleed from the arm, and follow that, perhaps, by the local abstraction of blood—leeches; you must apply cold, and adopt the other parts of the antiphlogistic treatment. During the time you are doing this, the limb should be laid on a soft pillow, or perhaps upon a long broad splint, duly padded, and arranged so as to prevent the fractured ends of the bone from moving on each other. There has been a dispute (in fact almost all points in the medical profession have been disputed) whether it is proper to bleed in cases of compound fracture or injuries of this kind; and one of the principal reasons that has been brought forward against bleeding is this—that in the progress of the case, in order to repair the injury which the accident has produced—in order to unite the bone—in order to remedy the consequences of inflammation, suppuration, and so forth—the patient will require considerable powers to counteract these depressing causes; and therefore you ought not to take blood from him—you ought not to run the risk of lessening those powers, the exercise of which will be so much needed in the future progress of the case. It seems to me, that the reason for bleeding is in order to *prevent* the inflammation and suppuration which, in the further progress of the case, are said to require this constitutional power. If you adopt suitable antiphlogistic treatment, such inflammation and such suppuration do not occur; so that the demand is never made upon those constitutional powers. The reasoning which objects to bleeding, in consequence of the extensive suppuration which will take place in the progress of the restorative process, seems to me to come to this:

if you do not bleed, inflammation and suppuration will ensue, and you want power, in order to repair the effects of these processes—you are not to bleed, because you will want that power. This is a mode of reasoning in which I cannot coincide; the occurrence of inflammation and suppuration, inasmuch as they are not checked—in point of fact, the neglect of proper antiphlogistic means—is made a reason why these antiphlogistic means should not be instituted. But the only ground for adopting this treatment is the expectation, or I should say certainty, that it will prevent the occurrence of the inflammation and suppuration, which are supposed to require such constitutional power to carry the patient through them.

It is by no means invariably necessary to bleed *generally* in cases of compound fracture. General bleeding probably is only required in some few instances, where the patient is robust—where he is of that kind of constitution in which the occurrence of considerable inflammation may be reasonably expected. In the majority of instances it will be sufficient to bleed freely from the part—to apply leeches repeatedly, until the probability of inflammation shall have passed by.

If, in a few days after the occurrence of the fracture, pain and swelling should come on—if the patient should begin to feel hot, feverish, and thirsty—you then would adopt the same kind of antiphlogistic treatment that I have just mentioned; for you have still the same object in view. Until all increased action and all probability of considerable inflammation is at an end, you will not find it expedient, in cases of compound fracture, to bind up the limb, or to confine it tightly by splints; in fact, close confinement and the firm application of these hard substances, are much more likely to increase the disposition to inflammation than to be of any service. I think, therefore, that until all risk of this kind is gone by, you should adopt very gentle means for retaining the ends of the broken bone in contact; and in compound fractures—particularly those of the leg—I think nothing answers better than what is called a fracture-box.

[Mr. Lawrence here exhibited one.]

The sides and ends admit of being altogether or partially opened. The limb rests on a soft pillow at the bottom of the box, and is supported at each side by two pads; and the foot is similarly supported by a pad at the end. Then the fracture-box is so constructed that it can be opened at different parts, and can be fastened again, by buckles and straps, just to any degree of firmness that may be requisite. It prevents such movement as would be painful to the patient; by altering the thickness of the pads, or by putting an additional pad in any situation, you can produce pressure where you

want to confine the bone, or prevent it from deviating in any particular direction. By opening one side of the box at a time, you may dress the wound, if it be on the side of the limb, and you may apply poultices or dressings very conveniently. If you have the pillow and side pads covered with a piece of oil cloth or silk, you keep them clean, and you find the limb is rendered exceedingly comfortable by this kind of apparatus. In many cases, the limb goes on so well after these compound fractures, that one prefers leaving it in the box to putting it in the ordinary splints. However, after the inflammation has gone by, when there is no longer any risk of that kind, the limb may be taken out of the fracture-box, laid upon splints, and confined in the usual way.

The progress of a compound fracture is often retarded by the separation of a portion of the broken bone. The ends of the bone being pretty completely denuded, sometimes perish, so that the part must be completely separated before the union can commence; and you are no doubt well aware when a part of the whole thickness of the tibia, for instance, has to be removed by absorption, that a considerable time is necessarily requisite; however, after this is accomplished, you find the union of the bone takes place perfectly. Although a considerable piece may come off each end of the broken bone, as in the case of the tibia, the resources of nature are sufficient to supply what is lost, or at all events to ossify the soft matter which intervenes between the ends of the bone, so as to render the union sufficiently strong to bear the weight of the body.

There was a case in the hospital during the last summer of rather an elderly person, between 50 and 60, who had received a bad compound fracture of the leg, in consequence of jumping out of a window, the house being on fire, where considerable inflammation took place, and where a piece of the whole thickness of the tibia separated by exfoliation, but where the bone afterwards united.

It may happen that the bone is comminuted in the situation of the fracture—that some portions are completely detached and quite loose, or if not, that they are merely connected by some slender portion of the soft parts. When such portions are lying loose, and near the surface of the wound, it is better to remove them at once; they are only sources of irritation and inconvenience if they are left behind. You are not, however, to make any extensive incisions in order to remove them;—I speak only of fragments that are entirely, or so nearly detached from the bone, that they admit of removal without such incision, and without giving much pain to the patient.

I should have observed to you that sometimes, if the end of the bone has been forced through the skin, you will find a difficulty

in restoring it to its situation,—it is so completely held or girt by the integuments, that in some instances we cannot replace it. Under such circumstances, there are two courses of proceeding. It may be necessary to enlarge the wound of the skin a little, so as to gain the power of replacing it:—or, in some instances, we find it advantageous to saw off the projecting point of bone, in order to admit of replacing, and bringing the fractured ends into proper apposition.

In respect to the inflammation which frequently comes on in compound fracture, when matter forms in consequence of such inflammation, it is expedient, as early as we can, to make an effective opening for its discharge. The matter in this case often forms deep in the limb, and if we do not produce an entire discharge of the matter, it is apt to extend in the limb, to run in the intervals of the muscles, and to produce extensive sinuses or excavations, which are afterwards very troublesome, and the source of long-continued suffering. A free and early opening, therefore, is particularly proper in cases of inflammation and suppuration occurring after compound fracture.

It may be a question whether it would be proper to proceed to amputation, if we are certain that the fracture extends into a joint. Now such a circumstance does not render amputation necessary, if the fracture have no immediate external communication. The process of restoration necessary to the consolidation of the fracture will go on very well, and the case do nearly as well as if the fracture did not extend to the joint. It may happen that inflammation of the synovial membranes may ensue, in consequence of the extensive injury which occurs either in simple or compound fracture; but such inflammatory affection of the joint may be combated by antiphlogistic treatment, and therefore such an injury is no ground for proposing the loss of the limb. Would it be expedient, or is it necessary, to propose amputation in cases of fracture extending into the joint with an external communication? If there were a large and extensive opening into a considerable joint, it might be necessary; but the mere circumstance of such continuation of fracture into a joint not of the largest size, does not of itself by any means furnish a reason for amputation.

In the course of last summer, there was a patient in this hospital with a compound fracture of the lower part of the tibia; the bone was in fact comminuted, in consequence of a heavy mass of stone falling on the limb. After a little time, a portion of the bone came away, consisting of part of the internal malleolus; in fact, the bone was comminuted in that situation; but the patient recovered very well. There were no symptoms of any consequence resulting from the extension of the fracture into the joint. The portion of the

bone involving the articular surface having been separated, the joint was rendered stiff, but no other circumstance that was at all particularly unfavourable occurred.

Now when you consider how extensive the mischief is in many of these cases of compound fracture, you will easily understand that the consolidation of the bone and the reparation of the injury altogether, require a longer period than is found necessary in cases of simple fracture. Eight, ten, or twelve, or even a greater number of weeks, often elapse before the fracture is consolidated. And again, from the long confinement, from the inflammatory swelling which the parts have undergone, from the deposition into their texture consequent on the inflammation, so much swelling and stiffness ensue, both immediately around the fracture and in the neighbourhood of the contiguous joints, that the limb, after the accident may be said to be cured, often remains in a state of very little use to the patient for a considerable length of time. In this state, friction, bandaging, surrounding the limb with strips of soap plaister, warm bathing, stimulating liniments, and exercise of the parts,—these are the means which, together with the natural process of absorption, ultimately restore the use of the limb.

OBSERVATIONS

ON THE

ANATOMY, PHYSIOLOGY, AND DISEASES OF THE CRYSTALLINE LENS,

And their Treatment.

By RICHARD MIDDLEMORE,

Assistant-Surgeon to the Birmingham Eye Infirmary.

[Continued from page 334.]

Causes of Cataract.—In alluding to the causes of opacity of the lens, I must refer to my opinion respecting its vascularity. I have said, that deriving its vessels from the capsule, it must be greatly influenced by the condition of that membrane; being loosely organized, it cannot endure much excitement; its death speedily follows augmented action, or imperfect supply. Are we to consider a thoroughly opaque condition of the lens equivalent to its death? I believe this opinion to be correct. The cataract of infants—congenital cataract—would seem to be a consequence of defect in the formative process: we observe that such a lens is milky and

diffused, and does not increase in density with the growth of the body. We know that a part may have vessels, and a circulation vigorous enough (although peculiarly adapted to the parts they supply) to form, but not to support the structure so formed. In illustration of this fact, let us instance the organization of an adventitious structure. We find a mass of lymph, a membrane, a mere film, or a clot of blood, increase and form a regularly-shaped tumor, and then suddenly slough. Congenital cataract would appear to be owing to a similar process; the circulation in the lens is not ample enough to support the structure its vessels have formed. In old age, when the circulation declines in power, a gradual obliteration of the vessels of the lens follows, and opacity becomes slowly developed—first in the centre, where they are most minute, and most distant from the source of impetus: and here I would remark, that the very great induration of this part sometimes noticed, may depend on a thickening and induration of its vessels. Whether this induration and thickening depend on ossific deposition, to which the arteries of old persons are subject, it would perhaps be difficult to determine; but reasoning from analogy, such would appear to be the case. The central opacity, a speck almost too minute for observation, would appear to depend on the incapacity of the vessels to preserve their action; but the destruction is limited in extent, in consequence of an ample and more vigorous circulation at the circumference than in the centre. The same languor of circulation, it is reasonable to suppose, exists here, in that part most remote from its source, as takes place in other parts of the body. If the lens become dislocated, if it be separated from its vessels, it quickly becomes opaque; like other parts, it perishes when deprived of its circulation. If inflammation be excited in a part loosely organized, death quickly takes place. This observation particularly applies to the lens. When, from injury or any other cause, the action of its arteries is greatly excited, its vitality is rapidly destroyed, as is evidenced by its very speedy conversion into an opaque substance, and, like other dead parts, it then ceases to perform its functions; it is no longer able to transmit and refract the rays of

light. Dr. Abercrombie has observed, that the brain becomes softened after it has been acutely inflamed: for this, amongst other reasons, he is inclined to believe that softening is, in fact, death of the brain; but he has laid down no rule by which to judge of its degrees of vitality—he does not say what degree of softening is essential to the entire loss of its life;—indeed, before the existence of such a state, dissolution must obviously take place. I allude particularly to this circumstance, as it correctly describes the mode in which that structure evidences its death. Can we deny to the lens a peculiarity of appearance, when deprived of its vitality, different from that of other structures from which it differed during its life? From these observations it would appear that cataract may arise from a defect in the formative process, the vessels of the lens not being sufficiently large and numerous to support it—(the human system is full of occasional evidences of the imperfections of nature in the lesser parts of her work, in her want of adherence to the perfection of her model in minor points, but important defects are seldom observed)—from the gradual obliteration of vessels in old age—from accidental violence, but not by occasioning opaque deposition—and from concussion by lacerating its vascular connexions. Mr. Wardrop, in the second volume of his “*Essays on the Morbid Anatomy of the Human Eye*,” asserts his belief that senile cataract may be owing to a want of balance between the functions of secretion and absorption; but if this opinion were accurate we should have, instead of a lens opaque and nearly as large as in adult life, one diminutive in size, but possessed of transparency. The function of absorption seems to be less liable to interruption than any other: the emaciation and attenuation of old age, and other evidences of loss of structure, amply testify the activity of absorption compared with secretion, at that period of life.

I am not acquainted with any means by which the progress of cataract can be arrested. This in itself furnishes a strong argument against the supposition that chronic inflammation of the lens, by occasioning opaque deposition, produces cataract—the slowly-advancing cataract of old age. Unfortunately for

the advocates of this opinion, old age is not the season when inflammation would be expected to occur; nor, if it did take place, would it be beyond the reach of treatment. We are able to subdue inflammation of other parts, in people advanced in life; why should the lens alone be beyond the reach of remedies?

If my view of the subject be correct, nothing short of an operation can restore vision. During the progress of simple, uncomplicated cataract, belladonna may be used for the purpose of expanding the pupil, by which the thin and least opaque portion of the lens will be exposed to the action of light;—in this consists our chief, if not our only means of palliating the defects it occasions during its advancement to maturity. Before proceeding to describe the operations best suited to the various forms of cataract, it may be well to say a few words concerning prognosis. Our prognosis will be favourable, if a patient with congenital cataract, and no obvious malformation of any other part of the eye, is able to distinguish light from darkness, and a weak from a strong light; or if a cataract takes place slowly in the otherwise healthy eye of a patient between the ages of fifty and sixty-five. Our prognosis will be doubtful, or unfavourable, if it arise from accident which has at the same time injured the deep-seated texture of the eye, or if it be connected with iritis or disease of some other important part, or take place in very advanced life; or if it be combined with amaurosis or glaucoma, any adhesions to the iris, a contracted pupil, a narrow anterior chamber, a broad areus senilis, an absorption of vitreous humour, or hydrophthalmia. It has been asked, why is not an operation undertaken as soon as, or soon after, cataract unequivocally evidences itself? Why permit a patient to remain for months, or even years, with just sufficient vision to render darkness visible? If an operation be undertaken at the commencement, when a patient has the power of distinguishing large objects, and should not be successful, we may be exposed to the reproach of having deprived him of a certain degree of comparative comfort; his condition after having undergone the anxiety, pain, and confinement of an operation, being worse than prior to its perform-

ance. It seems probable also that a greater degree of inflammation is likely to be excited by interference during the progress than at the close of morbid action; it is therefore prudent to wait until all useful vision is quite lost.

For children, delicate and old people, the only preparative treatment required will be a little aperient medicine; one or two doses, so as to clear out the alimentary canal, will be quite sufficient for the purpose;—but in adult and middle age, in the strong and phlethoric, a course of preparative treatment is necessary. The patient should be bled and purged, the diet should be lowered, until a reduction of the general fulness of the system be effected. If any irritability of the eyelids, tinea or chronic ophthalmia, be present, it should, as far as possible, be removed. In short, irritation of the eye, disorder of the general health, and fulness of the system, are circumstances unfavourable to the successful result of an operation, and ought on that account to be removed prior to its performance.

Cataract is generally removed by one of the following operations: extraction, solution, depression, and keratonyxis. Extraction should be preferred whenever the lens is hard, the anterior chamber ample, and the cornea of its customary size. Solution is required when the lens is soft, when the capsule has contracted extensive adhesions to the iris, or the latter membrane to the cornea, when the lens has become absorbed, and a portion of the capsule alone remains, or when the cornea is small, or the patient so old and feeble that the union of the corneal flap may not be expected to take place. Keratonyxis is suited to cases where the cataract possesses an unusual degree of softness or milkiness, or where partial absorption of the lens has taken place, in consequence of accident, in which a mere touch with the point of a couching-needle will be sufficient to ensure its removal. This operation is quickly and easily performed; and as no deep-seated parts are injured by it, it is followed only by a very trivial degree of inflammation. I object to depression, for a variety of reasons: we are unable to limit the extent of the depression, we cannot tell how far the lens may be urged; if it be forced against the retina, serious inflammation may arise, and a train of

evils horrible to contemplate. The cells of the vitreous humour must be lacerated, and the operation may be rendered fruitless either by its resuming its position or by its irritating effect upon the iris.

Mode of performing the Operation of Extraction.—Let the patient lie upon a table, near to, but not opposite the window, with the head somewhat raised and the face turned obliquely to the right side (supposing the left eye to be the one selected for operation); an assistant gently raise the upper lid, and, without making any pressure upon the eye-ball, fix it against the edge of the orbit. The operator then resting his right hand upon the cheek of the patient, and holding Beer's knife with the thumb, the index, and the middle fingers, and depressing the lower lid with the left, passes it somewhat inwards, as though he intended to transfix the iris at a little distance from its ciliary attachment; when (having passed it quite through its layers) it should be turned in a direction parallel to the iris, and by a gently propelling action of the fingers, or more properly by their extension, urged through the opposite side of the cornea, at about the same distance from its junction with the sclerotica, at which it entered. The propelling action of the fingers being now continued for a short time, the whole of the cornea will be divided, with the exception of a small portion at its lowest part. By a slow, steady, downward movement of the knife, this division will be readily effected. Some operators prefer to press the nail against this small portion of the cornea, in order that it may be more correctly incised; a practice to a certain extent objectionable, inasmuch as the cornea is bruised as well as divided, by the pressure of two hard surfaces. During this process, the eye of the operator should carefully watch the point of the knife, for on its accurate guidance mainly depends the quality of the incision.

As soon as the cornea is divided, the assistant should be directed to drop the eyelid and gently rub the cheek, so as to quiet that spasmodic action of the muscles which is apt to follow the incision of the cornea. When the patient has recovered from the pain of this part of the operation, the assis-

tant must again carefully elevate the lid, avoiding all pressure upon the eye-ball. The operator having depressed the lower lid, carefully introduces beneath the corneal flap a slightly curved needle, with its convexity upwards, until it reaches the centre of the pupil; its point must then be directed towards the capsule, and moved in various directions, so as to lacerate it freely. The instrument must now be withdrawn, with its convexity downwards, and the eyelids closed as before. In a few minutes the lids should again be separated, and, if the lens remain in its situation, the flat end of the curette should be laid in a transverse direction upon the upper and back part of the eye-ball, and gently pressed upon it, taking care that the pressure be so gradually applied as not to urge the lens through the pupil with a forcible jerk, but gently and slowly to raise it, to tilt its edge over the lower loose border of the iris. If, on the application of pressure, the vitreous humour seems inclined to project, and the upper edge of the lens declines, it would be advisable to pass a fine hook into its substance, and gradually withdraw it.

If the first puncture of the cornea be made in too perpendicular a direction, the iris may be transfixed, and the consequent abrupt turn of the knife, so as to place its flat surface parallel to the iris, will be likely to bruise the cornea, and, by enlarging the opening, to permit the premature escape of the aqueous humour. If it be made in too oblique a direction, the internal division will by no means correspond with the external, and will probably not allow of the passage of the lens, besides leaving, in the event of union, a broad cicatrix, which may greatly obscure vision; or, what is worse, the point of the knife, instead of passing through, may pass between the layers of the cornea; an accident very likely to induce a permanent opacity or sloughing of that tunic. If the incision should be too small, either from the first puncture being made much below the diameter of the cornea, or from the point of the knife coming out too soon, or from the lower section being made too distant from the junction of the cornea and sclerotica, it would be advisable to enlarge it, rather than endanger the laceration or inflammation of the iris by urging the lens through

an opening too small to admit of its easy transition.

Operation of Solution.—The patient being placed as for extraction, the eye not to be operated upon being steadied by the pressure of a bandage, and the assistant having fixed the (left) eye, and raised the upper lid by means of a speculum, the operator, holding between the fingers and thumb of the right hand a fine couching-needle, passes it through the sclerotica, about a line and a half from its union with the cornea, and rather below its diameter (on account of the ciliary artery), obliquely towards the optic nerve. Having transfixed the sclerotica, the handle of the instrument should be gently depressed, and its point brought in front of the cataract and moved in various directions, so that the capsule may be freely lacerated, the lens broken, and some of its fragments placed in the anterior chamber. The needle is now to be gently withdrawn. It is of great consequence to use a very fine and sharp needle, and never to move it about so freely or so extensively as to incur the risk of doing much injury; bearing in mind, that it would be far preferable to repeat the operation again and again than provoke great inflammation, by an absurd attempt to render the first operation effectual. The needle I think preferable, is small in size, flattened towards its extremity, and sharp at its sides and point.

[To be continued.]

LITHOTRITY.

To the Editor of the London Medical Gazette.

SIR,

HAVING already forwarded to you, at different periods, papers on the action of the principal instruments, and the method of employing them, translated from the MS. of Baron Heurteloup, I now send you some considerations on the various circumstances which influence the operation and enable the surgeon to decide on the propriety of operating by the lithotritic instruments. This chapter has appeared to me to contain much valuable information, and

I trust will prove acceptable to such of your readers as take any interest in the subject.—I have the honour to be, sir,

Your obedient servant,

J. RUTHERFORD ALCOCK.

May 21, 1830.

On the Circumstances which contribute to the Success of the Operation of Lithotritry, and on the Conditions which render it difficult or inadmissible.

[Translated from the Manuscript of BARON HEURTELOUP.]

As soon as the lithotomist determines that a patient ought to undergo the operation, it may be performed without further consideration or difficulty. Whether the bladder be wide or contracted, the stone large or small, flat or round, adherent or not, the surgeon, with a cutting instrument, is always able to penetrate into the organ where the stone has been deposited, and, by the opening which he makes, remove the calculus if it be small, or tear it out if of large dimensions. The varieties in the organs which are observed, or any peculiarity of formation, temperament, &c. are of slight importance to the surgeon performing the operation of lithotomy. With an instrument cutting his way, and ready to use direct force, all obstacles are soon removed, for they cannot be of a nature to resist the powerful energy of the instruments which he employs.

The lithotritic surgeon, on the contrary, whose object is to cure the patient by gentle means, and who is forbid any kind of violence, has to thread a narrow passage with his instruments, manœuvre them in a soft circumscribed organ out of sight, and then act upon a stone of which his only knowledge must have been acquired by the touch; and who, to obtain the cure of his patient, has to count upon the expulsion of the fragments by the natural efforts of the bladder and by the narrow passage nature has intended for the ejection of the urine. He must necessarily meet with difficulties proportionally greater, as the means he employs are more gentle and allow of less violence. He feels himself compelled to weigh and consider numerous details which are of no importance to the lithotomist, but nevertheless, when he proceeds to the practice of his art, become the subject

of considerations of the greatest interest; for acting by dexterity rather than force, he ought to turn aside obstacles, and not remove them.

These are the points which we will endeavour to present to the attention of our readers with arrangement, in order that they may be enabled to appreciate the circumstances which determine the greater or less propriety or impropriety, of submitting a calculous patient to the operation of lithotritry. We will first consider this subject as influenced by age; 2dly, the constitution or general habit; 3dly, the state of the urethra; 4thly, of the prostate; 5thly, of the bladder; and lastly, of the stone.

Of Lithotritry considered with relation to Age.

If lithotritry has been introduced for the purpose of avoiding the danger of the common operation, it must lose in importance when considered in relation to children; for it is observed in lithotomy, practised on children from six to seven years, or even from seven to eight, the results are not nearly so frequently fatal as in the adult, and still less in old age.

This observation naturally inclines us to be less disappointed that lithotritry is not nearly equally applicable in children as in those of more mature age.

If we return to the examination of the basis by which we have established, that lithotritry will always be employed with advantage under proper circumstances, we shall readily perceive how rarely children will be found in such favourable condition. We have said that lithotritry will be more frequently attended with success in proportion as the patient shall present himself to the surgeon nearer the beginning of the disease. In this view children are unfavourably situated, for it seldom happens that the persons about them attend to the inconveniences which the stone may cause at the commencement. An adult is at once aware of the unpleasant sensation at the end of the penis, and observes immediately, by the stoppage in the jet of his urine at times, that there is some derangement in the urinary organs. A child, however, under the same circumstances, says nothing—probably perceives nothing, and complains of nothing. During the first three or four years, the calculus falls in the

bladder without one's being aware of it, and enlarges in this organ. If the sufferer has already attained the age of five or six years he complains sometimes, but this is rare; the sensation which he experiences he mistakes for a natural one, and endures it for a long time, until the instinctive movements, the result of this painful sensation, carried to a high degree, denote a state of suffering that cannot escape the observation of an attentive mother: it is remarked that the child often has his hands to the end of the penis, drawing it out and squeezing it to ease himself of the painful feeling; elongating it to such an extent as almost to constitute a disease. His urine stops suddenly while voiding it, he stamps while in the act, and his face becomes red; he cries and screams, is agitated, and often, when very young, convulsions supervene.

It is certainly impossible for all these symptoms to take place without exciting the attention, and determining the persons under whose care the child may be, to consult some one; and this is in fact what takes place, but not until the disease has already gone on to such an extent as to cause the symptoms to be strongly marked; and these symptoms do not arrive to this marked state until the calculus has attained the size of a peach-stone, or a small nut, and sometimes larger; for the calculus increases in size as quickly in children as in adults.

If we now consider, in extreme youth, how narrow is the passage through which the instruments are to be passed into the bladder, and more especially through which the fragments of the stone are to be expelled—how difficult also at that age it is to maintain, during the operation, that tranquillity and immobility which is necessary to enable the surgeon to employ the requisite tact and delicacy—we shall be able to appreciate, without weighing this subject much longer, how difficult the operation of lithotripsy must be in children, and how very considerably the favourable circumstances which often accompany this operation on the adult are diminished.

We must not forget that a stone which may be considered small in the adult is large in a child; for the size of a stone, with regard to lithotripsy, ought not to be estimated by an absolute measurement, but relatively to the

power of the instrument which has to destroy it, and the capacity of the canal which is to give passage to the fragments. Thus the largest of the instruments we can introduce into the urethra of a child under six or seven years, cannot exceed two lines, or two and a half in diameter; and the action of an instrument of this size is so weak and slow as to render it imprudent to attempt to reduce a stone of from ten to twelve lines in diameter into fragments sufficiently small to pass by the urethra; for this would require manœuvres, and repeated sittings, which would not be without danger.

Such are the considerations which lead us to conclude that, in very young children, the operation of lithotripsy will never be equally general in its application as in the adult; and the strongest reason for this is found in the difficulty of attacking the disease at the moment of its commencement, and also in the very great mobility to be encountered in all such patients.

Let not this decision, however, be taken in too absolute a sense; for we are very far from proscribing the application of lithotripsy in children. We believe, on the contrary, that it will be rationally applicable in those cases where the stone gives rise, soon after its fall into the bladder, to well-marked symptoms; and attempts to pulverize it will be attended with success, for the calculus will be in a fair proportion to the power of the instrument employed.

When, on the contrary, the stone has acquired a certain volume, we must recollect that lithotomy performed on children is not so dangerous as in adults, and that the pulverization of the calculus presents greater inconveniences and difficulties with respect to the organization and the slight development of organs in which we are to operate. Again, we must remember, that the question here is not whether lithotripsy is practicable in children of this age, but rather, if performed, whether it offers greater chances of success than lithotomy. This is what we doubt, whenever the stone has acquired the size of a hazel-nut before the age of three years, or a small walnut, if from the age of five to six, seven, or eight years.

It must be evident that these considerations are applicable to children in direct proportion to their age, and as they advance from the period of their

birth, they become less and less applicable; hence, as soon as they have arrived at their seventh or eighth year—the period at which they commence to analyze their sensations, and when they can appreciate the difference which exists in their urinary organs between a state of good health and that succeeding the formation of the stone in their bladder—the importance of lithotritry increases with respect to them, and each year which brings them nearer to the adult state, augments the favourable chances of relieving them by these means.

Facts have already supported this opinion, and science is in possession of examples of cure obtained by lithotritry in children of from seven to eight years' old: I have myself operated and cured one child of seven years and a half, who suffered from a stone of five lines in diameter. This is the only case in which I have thought it right to employ the lithotritic instruments in children under eight years, though several have been brought to me for examination. But the little patients had suffered a long time, and carried stones at the time of considerable volume, so much so that I declined operating by a method which I did not believe was the most sure means of effecting their cure.

The age most favourable to success in this operation is the adult; then all the organs are fully developed, the passages are large, the bladder spacious—its expulsive force is in its greatest vigour; sensibility is sufficiently developed, joined to a slight attention which every one of this age pays to the manner in which these functions are performed; all account for the fact, that the adult, more frequently than either infancy or old age, is found in the most favourable condition of having only a small stone to be destroyed, for, aware of its existence at an early period, and comprehending the means now offered of relief, they quickly have recourse to the lithotriteur.

Old people, setting aside the change that takes place in the contraction of their organs, and an age in which all the tissues lose their firmness, present, notwithstanding, considerable facility for pulverizing the stones; their canals are large; their bladders extensible and dilatable; there is no obstacle to the performance of lithotritry at this age, but it presents an inconvenience of

some importance, inasmuch as the power necessary to expel the fragments is often wanting. This want of energy, in addition to the laxness of the urethra and the vascular condition of the neck of the bladder, the result of organic changes effected by years, and sometimes aided by the presence of calculi, renders the expulsion of the fragments very difficult, if not impossible. In cases where this inability is observed, it forms a direct prohibition to the operation. Sometimes this want of power is shewn before the commencement of the operation;—when the patient evinces a habit of body marked throughout with the character of great debility;—when the urine drops gently out, falling between the feet, and especially when a gum elastic bougie is introduced into the bladder which contains urine, and it does not evince sufficient power to expel the liquid within it with any force. In this case, we must take good care not to operate if the stone have acquired any volume, that is, from 10 to 14 lines for example, for the fragments will not be expelled; they will exhaust the patient, and sometimes lead to accidents which the stone, if left entire, would not have caused. If, however, the stone be small, it may be broken up or reduced into very small fragments, which may be done tolerably quickly when only of the size alluded to; the expulsion of these particles may be excited by the introduction of a large silver sound, with large eyes, of which we will speak in another portion of this work, when we examine in a general manner the circumstances which attend the removal of the fragments.

We have by these means effected the cure of two old men, one aged 72 and the other 82, neither of whom retained the power of expelling the fragments. In a third, aged 82, we were compelled to desist from the operation, for the stones being in too great number, the introduction of the sound was rendered too often necessary, and consequently too painful. This patient afterwards underwent the operation of lithotomy.

At other times, the inability of expelling the fragments only supervenes during the course of the operation, after one or two sittings; the patient who expelled the fragments at first with difficulty and slowly, now utterly fails. We are then obliged to have recourse to the sound; but it must always be re-

membered never to employ it until there is a moderate quantity of fragments to remove, otherwise the patient will be too much fatigued; it is even better when the size or number of the calculi are great, to relinquish the operation, for we cannot hope it to be followed by any good result, if it be necessary to have recourse to the sound very often.

We see, then, with relation to the age of the patient, the operation of lithotritry leads to considerations of some importance; we see that, well adapted to cure adults, it becomes much more limited in its use as the patients on whom we would operate are at the two extremes of life.

Lithotritry considered in relation to the Constitution or general Habit of Body.

Obesity, which, when it takes place to a great degree, is sometimes an obstacle to the easy performance of lithotomy, presents no difficulty in the operation of lithotritry. Among the patients I have operated upon, one was excessively corpulent, a baker by trade, and I found that this, so far from increasing the difficulty of performing the different manœuvres of the operation, appeared to render them easier than in spare subjects, whom, at first sight, we should have been inclined to say presented a more favourable condition. In general, all other things being equal, the patients whose *embonpoint* is rather excessive, seem to afford greater facilities for the operation, more especially that part of it which consists in seizing the stone. I have also found in these patients greater facility in the introduction of the instrument. I have considered that these advantages were owing to the urethra being held more firmly, and its sides presenting less distinct cavities, these being filled up by the surrounding cellular substance—allowing the instrument less latitude of motion; and in depressing the instrument, I have found the greatest facility in seizing the stones, and more especially the fragments in fat subjects, owing to their bladders, when distended, having a more regular and rounded form, the base more elevated, and the stone in this kind of bladder is more conveniently placed with relation to the opening of the branches. This is evident in examining the distended bladder of a

fat subject, when this organ is in a healthy state. If the description I have already given of the bladder, more especially of the form of its interior when distended by urine, be recollected, it will be easily understood that the inequalities of this organ must be in direct proportion with the emaciation of the subject.

It must not be forgotten that I speak here of a case wherein the urinary organs are quite healthy, for we shall see that in disease and enlargement of the prostate, or in the case where the rectum is rendered voluminous by internal hemorrhoids, the bladder of a fat person, in proportion as it is filled with water, occupies less space in the lower cavity of the pelvis, which is in a great measure filled with adipose tissue, and hence is found more disadvantageously altered by these accidental circumstances than when they happen in spare subjects; for it is evident, that the less space there is in the organ, the more any cause which shall diminish that is a disadvantage. Emaciated subjects, when their organs are healthy, present, on the other hand, greater facilities for the breaking up of the stone, on account of the largeness of the bladder, which permits the branches of the instrument to be fairly extended, and full play to its action. This is especially favourable where a whole stone is to be crushed; but when we come to the later stages of the operation, that of seeking for the last fragments, it is not so easy to seize them as in the bladder of a person moderately corpulent. In spare subjects, the fragment is lodged under the neck, which, as we know, is of considerable depth, and the bladder being very large, having a wide base, the fragment no longer falls necessarily in the direction of the axis of the stone, for it remains either at the right or the left below the neck, and is the more troublesome to find, inasmuch as it is irregular, and not being spherical, like a small stone when entire, it does not roll to the *rendezvous*, as it were, where we find all small stones while they retain the round form: in whatever kind of bladder it may be in, a fat or an emaciated patient, this is an inch from the neck of the bladder, and constantly in the direction of the axis of the instrument.

An organic state of disease carried to a high degree, seems to form sufficient

grounds for declining the operation, especially when the stone has arrived at so considerable a size as to require the operator to return to the attack a great many times. Lithotritry in ordinary cases rarely gives rise to any degree of fever or organic derangement; but in a diseased subject, particularly where all the central organs are severely affected, this patient is more liable to the sympathetic derangement which sometimes ensues from the irritation caused in the urinary organs, by the manœuvres which the operation requires. Nevertheless, if the stone be small, so that it may be removed at two or three sittings, we think the patient may undergo the operation with advantage; but we are also of opinion that it ought not to be attempted unless a small stone should cause the patient great suffering. For the rest, it is for the surgeon to weigh the comparative advantages and disadvantages which lithotritry in such cases offers, and to employ or reject it according as the peculiar circumstances may lead him to decide. But we would particularly impress upon the surgeon this consideration—that the operation of crushing the stone in these cases, even when practised with the greatest care and gentleness, may produce sympathetic affections, which will spread from the diseased organ.

Whatever be the inconveniences, however, which lithotritry presents in these cases, they are not to be compared to those which result from lithotomy; which, besides, ought never to be performed in these cases. Thus we find in lithotritry a resource applicable with at least some chances of success to patients whose death would necessarily be the result of lithotomy.

Another condition may also prohibit the employment of the lithotritic instruments, or at least require to be well considered: when the question arises respecting a patient in whom there exists great disposition to acute calculous nephritis, and in whose bladder a number of stones are already formed, I cannot speak from experience of such a case and its results, since I have not yet had an opportunity of observing it; but if I may be allowed to judge by analogy, I should refer to the fact of a man suffering from gravel and catarrh of the bladder, which I treated by means of the sound, with which I injected water several times each day into the organ, after

having first emptied it of the urine, loaded with mucus, which it contained. This patient voided habitually gravel; which, after being formed in the kidneys, passed the ureters and fell into the bladder, from whence it was expelled with the urine. When I commenced making injections, I observed in the commencement some little improvement, but after a few days the pains in the kidneys increased, and gravel was voided in greater quantities. I stopped the injections and ceased introducing the sound; the pains diminished sensibly, as also the formation of gravel; but in the end, the catarrh continuing, I returned to the use of the sound. The pains and gravel returned, until, enlightened by the frequent return of the same phenomena, I perceived that there was a manifest correspondence between the appearance of the pains accompanied with formation of gravel; and the irritation which I produced by repeating the introduction of the sound daily, which, notwithstanding it was done with the greatest care, still always gave the patient a little pain.

This fact may give rise to the belief, that the irritation excited in the bladder may, by sympathetically communicating with the kidneys, determine in these organs that peculiar state which causes the formation of calculous concretions. This opinion may be further supported by the observation of several persons affected with acute gonorrhœa, who, during the time they had the urethra thus inflamed, voided red or white powder, which was deposited at the bottom of the vessel containing the urine. This deposit was remarkable, for among these patients some of them had never observed it in their urine, and others who had observed it during their lives, before they had contracted the gonorrhœa, had not perceived any vestige of this powder. It is also worthy of observation, that frequently after excessive venery the urine becomes turbid, and deposits oftener powder of uric acid than in the ordinary circumstances of life.

We conclude from this fact, that if the inflammation attacking the urethra and bladder can cause a more considerable formation in the kidneys of the calculous matter, this ought to induce us to examine attentively what advantages these patients may derive from the operation of lithotritry, before we

induce them to submit to it. Let it not be forgotten that we speak here of patients who have a calculous diathesis carried to a great degree, and have already several stones in the bladder, which would require for their removal a great number of sittings; for it is evident that a man having several small stones in the bladder, notwithstanding he may have a strong calculous tendency, these stones ought to be pulverized. In this case it is scarcely necessary to say that the patient ought to be placed immediately on the regimen most opposed to this predisposition, and especially to the attacks of acute nephritis, to which such subjects are very liable.

[To be continued.]

TWO CASES
OF
STRICTURE OF THE LARGE IN-
TESTINES,

About the point of the termination of the Sigmoid Flexure in the Rectum; with Observations.

BY JOHN BURNE, M.D.

CASE I.—*Scirrhus-contraction of the Large Intestine.*

A GENTLEMAN, between 45 and 50 years of age, of a sanguine and very irritable temperament, and accustomed to live well and keep late hours, consulted me in February, 1826, on account of some troublesome superficial small ulcers in the mouth, which had teased him for several weeks, and had resisted the remedial means employed. Accompanying these ulcerations was a taste of heat and dryness of the mouth and pharynx, with some little trouble in deglutition. The temperature of the body was increased and the surface dry, and the pulse was accelerated and rather tight; and the first hours of the night were passed restlessly, the bowels being habitually regular. The above assemblage of signs, except the regular state of the bowels, will be recognized as the frequent precursors of stricture of the œsophagus, which I thought it my duty to intimate to the patient, that he might be alive to such admonitions.

By the use of leeches to the side of

the throat, and by saline aperients, the ulcers healed, and all the other signs abated in about ten or twelve days.

In November of the same year, and in February 1827, I was again consulted by this gentleman, on account of some dyspeptic symptoms, which were soon relieved by medicine, his body being as usual, naturally and freely open every day. From this time, I saw nothing more of him for twelve months, when, in February 1828, he again applied to me, on account of his usual dyspeptic complaints, but with this difference, that his bowels, which had been exceedingly regular all his life, were now sluggish, and required the frequent use of aperient medicine. On this occasion, I prescribed the comp. rhubarb pill of the Ed. ph. which proved effectual, and together with other treatment, gave him so much relief, that again I heard nothing of him for five months, when, in July 1828, he called upon me, and complained much of flatulence, acidity, and irregularity of the bowels. He was this time also very much relieved by aperients, but the action of these medicines was not so certain as formerly; and when the bowels were not freely moved, he suffered much from fulness.

His symptoms, although relieved, returned whenever he relaxed in attention to the bowels; on which account, together with the favourable season of the year, I advised him to go to Cheltenham. The Cheltenham waters acted like a charm; the bowels emptied themselves freely every morning, and his appetite and digestion became exceedingly good, as did his spirits and general health; but immediately after he had quitted Cheltenham, the irregularity of the bowels returned, and with it all the dyspeptic troubles; and as from these he suffered considerably, and from his age and sallow face, and obstinate complaints, there was reason to apprehend that organic disease was establishing itself, I proposed a consultation, and the friends fixed upon the late Dr. Armstrong.

The Doctor and myself examined the abdomen very minutely, as I had done before, without being able to discover any indication of disease: pressure was borne in every part, and the only uneasiness complained of, except griping, was a pain which sometimes shot through the upper part of the sacrum. Blood was directed to be abstracted

from this part by cupping, and, in addition, an alterative aperient plan was agreed upon; but these measures not being followed by amendment, it was proposed to ascertain if any cause of obstruction existed in the rectum. On first introducing the finger into the gut, no trace of disease was discoverable, but by passing it forward as far as was practicable, I met with a hard immovable tumor the size of an egg, and further backwards and upwards, I reached with the tip of my finger, a contraction of the bowel, having an opening not larger than a swan quill, surrounded by a hard knotty structure, which altogether exactly resembled a schirrous os uteri.

The case was now made out, and I recalled to mind the tendency to stricture of the œsophagus, manifested upwards of two years before.

Saline aperients, diluted in imitation of Cheltenham water, were now prescribed, and succeeded very well in evacuating the bowels.

A mechanical obstruction having been discovered, it was deemed proper to take the opinion of a surgeon as to the practicability of giving relief by a bougie or otherwise, and the late Mr. Wadd was called in. On his first examination, Mr. Wadd did not reach the disease, but when after several days, he satisfied himself of its existence and malignant nature, he gave it as his opinion that surgery could do nothing. Saline aperients were laid aside and castor-oil substituted, which, although it excited the action of the intestinal canal, did not procure evacuations: the muscular efforts of the intestines were most violent, and gave rise to excessive spasmodic pain; the intestines could be seen and felt to move under the integuments, making ineffectual attempts to force the feculent matter through the stricture, and the agony was so great during these spasms, that the patient desired death. The spasms were much allayed by large doses of laudanum, but were, nevertheless, succeeded by a sharp attack of inflammation, which did not subside for several days; and when the patient had struggled through this danger, it was only to encounter similar torture at some early period. Extreme difficulty was always found in procuring evacuations, and being driven, as we were, to extremity, further surgical advice was desired, in order to consider, a second

time, the practicability of facilitating the evacuation of the colon. With this view, Mr. Copeland, Mr. Brodie, and Sir Astley Cooper, were consulted in succession, and all concurred with Mr. Wadd on the hopelessness of the case, and the inexpediency of surgical interference. Mr. Brodie and Sir Astley Cooper did make some attempts to pass a bougie, but did not feel justified in persevering, lest they should rupture the intestine.

Injections and saline aperients were had recourse to unremittingly with partial success; the violent spasms returned frequently, and the most severe were followed by inflammation. The violent contractions of the intestine constituting the spasms, were always more or less relieved by laudanum; but opium in this form made the mouth and tongue dry, and was followed by head-ache and languor. From these ill effects, the liquor opii sedativus was free, but the most efficacious preparation was the acetate of morphia in the form of a pill, and in the dose of from $\frac{1}{8}$ to the $\frac{1}{2}$ of a grain, repeated as circumstances required. The last preparation was found a most valuable medicine, and never failed to mitigate the excruciating pain and other sufferings of the patient's last days.

In this way the patient lived on, passing scarcely any feculent matter, and suffering pain and inflammation by turns till the 20th of February, 1829, on which day the spasms returned violently about six o'clock in the morning, and soon after seven the patient felt a sudden and dreadful pain dart from the left side across the belly above the navel, which he compared to the discharge of a pistol. Quickly afterwards the belly became tense, the respiration difficult, and the powers of life depressed. It at once occurred to me that the colon had given way above the stricture, which I stated to the friends, and prepared them to expect the rapid dissolution, which took place in the course of eleven hours.

Sectio cadaveris.—The abdomen being opened, a large quantity of feculent matter of soft consistence was seen lying among the intestines and upon the mesentery, and was found to proceed from a transverse rupture of the colon, about an inch long, at the spot from whence the violent pain darted. The whole of the colon was filled with fecu-

lent matter of the same kind; the sigmoid flexure was seen stretching across the brim of the pelvis to the right side, when it turned quickly upon itself, and terminated in the diseased portion, which was situated directly under the promontory of the sacrum. The diseased part was about the size of an egg, and consisted of a scirrhus degeneration of those structures of the intestine situated between the mucous and peritoneal coats. The aperture of communication between the colon and the rectum, through the diseased part, scarcely equalled the size of a swan-quill, and had a curved direction, which proved the correctness of the opinion, that force used in attempts to pass a bougie would be likely to rupture the bowel. The lower opening looked backwards and downwards to the hollow of the sacrum, and its margin was knotted and irregular, as has been described. There were adhesions of the sigmoid flexure to the small intestines, and the scirrhus mass was adherent to the sacrum.

CASE II.—*Annular Contraction of the large Intestine.*

Of the second case, which was an annular stricture, I regret that I am only able to present a few particulars, not having the means of obtaining the early history. It occurred in a female pauper in Covent-Garden workhouse, who had been admitted three weeks before her death, in a state of extreme emaciation, and with a remarkably distended flatulent abdomen; she passed scarcely any feculent matter during the three weeks, and was constantly vomiting, so that nothing, except brandy and water and similar beverage, could in any way be retained on the stomach.

Section cadaveris.—Before the abdomen was opened, traces of the convolutions of the intestines were evident, by corresponding elevations of the integuments: these convolutions were found to be distended with gas, and the colon was full throughout of soft feculent matter; and at the termination of the sigmoid flexure in the rectum was a circular contraction of the bowel, forming the annular stricture. There was no thickening or disease about the part, and the contraction had the appearance of the bowel tied with a ligature, except that there were neither folds nor puckering.

Observations.—The ulcerations, the heat of the mouth, and trouble in deglutition, detailed in the history of the first case, shewed a condition of constitution prone to morbid action, which, having first fixed on a part of the digestive canal, determined that canal to be the eventual seat of disease.

A very prominent circumstance in the dissection of both these cases, was the soft consistence of the feculent matter, particularly when it is remembered that, from the slow accumulation, the feculent matter had been lying in the colon for several weeks in the first case, and in all probability for several months in the second. This is the more curious, because in ordinary constipation of the bowels, the feculent matter becomes hard and knotty in eight and forty hours, sometimes in twenty-four, and continues so till it is evacuated; hence it occurred to me that the soft consistence above alluded to, was probably one of those remarkable provisions which nature is often observed to make against disease, and if this is the case, the same soft condition of the retained feces may be expected in all cases of stricture. Experience, however, does not afford me a sufficient authority of facts to come safely to a conclusion on this point, but the probability which I have expressed is much strengthened by two cases, one of which occurred in private practice, and was mentioned to me by Mr. —, a pupil of Guy's Hospital, who witnessed the dissection; and the other in a patient in the same hospital, in both of which the accumulated feces were in the same soft state. I do not know that this circumstance has been hitherto noticed, nor can I find in the works upon stricture of the rectum any evidence that bears satisfactorily on the question.

Did the feces undergo the same change as in ordinary cases of constipation, there would be no possibility of evacuating them through a stricture, and the irritations and accumulations would be quickly and uniformly fatal; whereas the reverse is a matter of daily observation. The sympathies by which this usual change in the feces retained in the colon is prevented, are the more remarkable, because they influence only the part of the large intestines above the stricture, for the soft feculent matter which gradually oozes through the contractions into the gut below, very

soon becomes solid and figured, as I had an opportunity of witnessing in the first case, in which it was not uncommon for solid figured pieces to come away, although all above the stricture was quite soft, as seen by dissection. This last fact is also mentioned by Mr. White*.

The soft feculent matter was also of a most healthy character, being homogeneous, and containing an abundance of good bile: from which it may be concluded that digestion was perfect, notwithstanding many of the symptoms said to be indicative of indigestion were urgent, as flatulence, fulness, acidity, and eructations; whence it is apparent that the sufferings usually referred to the stomach, may arise from another cause than disorder of that organ.

In both instances the patients died from the mechanical obstruction: in the one the disease was not malignant, in the other the malignancy had not come into operation, the patient having died before the destructive effects of cancer had taken place, as ulcerations, sloughing, discharge, and sympathetic irritations and fever: the subject for consideration, therefore, was the treatment of the obstruction; the observations on which refer only to the first case.

The eminent surgeons consulted were unanimous as to the inexpediency of attempts to force a passage by the bougie, owing to the situation as well as to the malignancy of the disease; in which opinion all must concur, who have witnessed the torture that attends the use of a bougie in scirrhus disease of the rectum, and which is not recompensed by any benefit: this stricture not admitting of dilatation, the effect of the bougie is to bruise and hasten ulceration, or increase it, if present. Although the most desirable means by way of operation, was the introduction of a hollow tube through the stricture, to facilitate the passage of injections, yet this was found impracticable, the distance of the strictured part from the anus being too great to admit of the finger as a guide, and without this, the capacious and yielding rectum left no chance of effecting the passage of such an instrument. In this dilemma, and in my frequent consultations with Mr. Wadd, I sug-

gested for discussion the propriety of making an artificial anus, which, although he discouraged, I cannot but think might be attempted under favourable circumstances as regards the operation, and urgent circumstances as regards the prolongation of the patient's life.

It may be said, that between the two evils of a stricture and an artificial anus, it is difficult to choose; to which I assent generally; but when the patient's life must fall a sacrifice to the mechanical obstruction, and when the prolonging his life for a few months only is of great consequence to his family, the suggestion is worthy the consideration of surgeons; for in the first case, the malignancy of the disease would not have destroyed life for months, in all probability; and in the second case, there being simply an annular contraction, life would have been preserved by an artificial anus, which would have permitted the regular evacuation of the bowels. To render the operation justifiable, the colon should be empty, and the means of attaining this end are the object of the medical treatment of stricture generally.

All are agreed that the aperients which must be necessarily given, should be of a mild character, and the recommendations of authors who have treated on the subject, are limited to castor oil, senna, and sulphur; thus leaving unnoticed saline aperients, which, as will presently be seen, are the most efficacious. These medicines, castor oil, senna, and sulphur, although desirable from their mild qualities, are very uncertain and ineffectual in cases of stricture: it is true they promote a moderate, and so far, a proper peristaltic action of the intestines, but as they do not render the fæces watery, this action is not followed by sufficient evacuation, and therefore not by sufficient relief. Sulphur is objectionable on other grounds: it has been known to form into balls when taken in large doses, and in this way may add to the mischief. The same objection applies also to magnesia, which has been found accumulated in a large quantity above the stricture.

While the subject of the first case was at Cheltenham, and taking the waters, the evacuations were so thin that the colon emptied itself effectually every day, and under these favourable circum-

* Observations on Stricture of the Rectum, 3d edition, page 37.

stances the patient lost all complaint and improved surprisingly. This first suggested to me the use of saline aperients, which were given in the form of Seidlitz powders and of sulphate of magnesia, in a very diluted solution; and they were found to operate much more pleasantly and efficiently than other aperients. These, however, and the Cheltenham water itself drank in town, were by no means so certain in their operation as the waters drank at Cheltenham, owing, no doubt, to the want of auxiliary circumstances which are to known to favour the operation of mineral waters, as change of scene, absence from the fatigue and anxiety of business, early rising, and exercise. On one occasion, when castor oil was substituted for salts, its effect was exceedingly injurious; it duly excited the action of the intestines, but as it did not render the fæces watery, they could not pass the stricture freely, and the consequence was violent spasmodic pain and vomiting.

Drastic and heating purgatives are very properly objected to in all cases of stricture; nevertheless, the distress of the patient on one occasion was so great for the want of evacuations, that a person of very great practical attainments was induced to propose the administration of croton oil, the propriety of which was much discussed, on account of its irritating properties and violent action; but its employment being much urged by the proposer on the score of its unrivalled purgative power in other cases, it was exhibited in the dose of one drop, which was repeated in the space of half an hour. The effect, as was anticipated, was nearly fatal; it produced most violent contractions of the intestines, and spasmodic pains, with a distressing heat along the whole alimentary canal, and constant and urgent, but ineffectual efforts, to go to stool, the scanty evacuation consisting of nothing more than a bloody secretion from the rectum, the product of excessive irritation*. The violent action of the intestines led one to fear a rupture of the colon, of which

the sequel of the case proved there was great danger.

In the medical treatment of stricture of the large intestine, then, saline aperients are the best and most efficacious; and where the disease does not admit of relief by surgical interference, the physician would best consult the interest of his patient, by urging him to reside at Cheltenham or Leamington, and by the aid of warm bathing and of drinking the waters regularly, to avail himself of the means which will most certainly mitigate his sufferings and prolong his life*.

DUTY ON THOSE ENTERING THE MEDICAL PROFESSION.

To the Editor of the London Medical Gazette.

SIR,

I NOTICED a letter in your journal of last Saturday, signed "A Surgeon and Apothecary," recommending that some heavy fee should be imposed on those who entered this noble profession. Now, sir, I ask you whether the practical fulfilment of such a plan would at all benefit us? Would your correspondent have the profession filled with no one but peers and marquises? Let him remember how many men have risen from the lowest occupations to the most splendid fame—men who perhaps had not two hundred shillings, much more pounds to give away when entering the profession. Let him consider how many geniuses he would have quashed; how many talents he would have been the means of rendering obscure; and I think he will then consider that his argument is without foundation, his proposal without judgment, and his publishing it a still greater proof of his rancour towards poor but well-educated students.

I am, Sir,

Your most obedient servant,
A WELL-WISHER TO THE GAZETTE.

[We do not feel called upon to volunteer an opinion on all the subjects discussed in the pages of the Gazette, but as our present correspondent makes an especial appeal to us, we have to state,

* As from the vast accumulation of feculent matter found on dissection it was impossible that any particle of the croton oil could have reached the rectum, the excessive irritations must have been the result of sympathy, which may go far to explain the phenomenon of the inflammation of the rectum, which occurs in cases of poisoning from arsenic.

* Midland Medical and Surgical Reporter.

that though we think the letter of "A Surgeon and Apothecary" contained some very just observations on the present state of the profession, yet his plan of obviating the evils of which he complains, is neither politic nor practicable.—E. G.]

COLLEGE OF PHYSICIANS,

To the Editor of the London Medical Gazette.

SIR,

I AM rejoiced to find, by an article in your valuable journal for the 1st May, headed, "College of Physicians," that curiosity; the grand promoter of information, has been excited in the mind of a Licentiate of the College of Physicians of London, with regard to the payment of an item of 32*l.* included in the admission fees. Your correspondent very naturally asks, *if this sum, or any part of it, goes to the support of the library?* which you answer in the negative: what then becomes of it? The fees to the president, censors, registrar, beadle, &c. &c. are quite independent of this sum. If it be to preserve the privileges of the members of the College, and to secure to them, and to them alone, the medical practice of London, it totally fails, as we every day find members of the College of Surgeons prescribing in cases purely medical, when we well know that neither their education nor their examination is by any means adequate to their engaging in *medical practice*. The candour of your observation with regard to the library I admire, at the same time I cannot help considering it a reflection on the College of Physicians of London. Surely such a College ought to keep pace with the science of the day, and every medical publication worthy to be referred to should be found in its library; which library ought, I conceive, to be for the use of the licentiates who are members, as well as of the fellows: for what licentiate would choose to put himself under a personal obligation to a censor for the use of the very library of the College with which he has associated himself? I trust, ere long, to see this, with many other apparent illiberalities, abolished, and hope the highly-cultivated minds of some of the fellows will in-

cline them to my way of thinking, for medicine is not now what it was in the days of darkness when the present College was founded; and the physicians who have most tended to promote medical science during the last forty years have certainly not found their majority in the fellows.

I am, Sir,
Your very obedient servant,
A LICENTIAATE.

27th May, 1830.

ANALYSES & NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abrégér."—D'ALEMBERT.

A Dissertation on the Influence of Heat and Humidity: with Practical Observations on the Inhalation of Iodine, and various Vapours, in Consumption, Catarrh, Croup, Asthma, and other Diseases. By JAMES MURRAY, M.D. M.R.C.S.

EVERY one knows the fondness with which a young medical man cherishes his maiden effort of authorship, in which he first puts forth his strength in support of some favourite theory, or some paradoxical novelty, by means of which he hopes to take the world by surprise. The dissertation now lying before us is pretty much of this description; it was originally an inaugural effort; the germ of it was a thesis presented at Edinburgh, about two years ago, for a medical degree; but it is now offered to the public in a very enlarged and comprehensive form, exhibiting a multitude of opinions on a multitude of subjects that have occupied the mind of the author during a lengthened experience. For though a young graduate, Dr. Murray is an old practitioner; he confesses to upwards of some twenty years novitiate at least, and of course has no particular claim on the indulgence of his critics. Neither do we think he requires it much; for though there are few points in physiology and practice that he does not touch on somewhere in his dissertation, yet it must be allowed that the bearings of his subject admit of great latitude, and are sufficiently ample to embrace a great

variety of topics without confusion or embarrassment. It is, in fact, a record of the opinions of the author entertained at an important period of his life—opinions very frequently fanciful and baseless, generally ingenious, but seldom or never profound.

The influence of heat and humidity is considered in a threefold point of view; and this induces a division of the work into three parts. Part I. treats of the effects of those agents on medical substances; Part II. their effects on food; and the last part treats of the influence of heat and humidity on the human body.

Our remarks and extracts shall be chiefly confined to this last part. It contains a theory of animal heat in addition to the thousand and one theories already in existence on the same mysterious subject. Dr. Murray's views are curious, although altogether conjectural; but lest we might not do him justice by a short sketch of his theory, we shall present the reader with some extracts from the book itself.

“Some experiments made on dilution and temperature lead me to conclude that the solids and fluids have, in a living state, a great attraction for water. In this manner I venture to account in a considerable degree for the continued *expenditure* and *renovation* of animal heat. If through the widely extended surface of skin and lungs, the blood receiving the aqueous vapour from the air, combines with and fixes it, in the state of simple water, or of new combinations of its elements with our solids and fluids, how much caloric must be thus set free? Suppose a given quantity of aeriform water in the atmosphere to be combining with the substances of our system, the absorption and condensation of this vapour will contribute caloric warmth to supply a considerable portion of the extensive expenditure of animal temperature. But if it be still further granted, that the skin and lungs have the power of taking up vapour, and that the blood chemically fixes this vapour, either in solid or fluid combination as a hydrate, the caloric of fluidity must then be disengaged. Add to fresh quicklime, or sulphuric acid, a due proportion of water, and you observe how abundantly caloric is liberated. As water forms a hydrate of lime, and gives out heat, why might it not be inferred, that it

may combine in the mass of our solids with the principles of their particles, and justify such language as a *hydrate of fibrin* in the blood and muscles, and a *hydrate of lime* or *gelatine* in our bones. Our mass of matter is almost entirely water; our elements absorb it on all sides.

“Though the laws of life sometimes are supposed to reject chemical regulations, and it is said we may have free carbonic acid and free caustic soda agitated together, but not joining in our veins, still the notion that the blood can unite the vapour of water from the air, in a solid state, with the principles of our bodies, is not improbable, even when the temperature is above that of the vapour itself which is inhaled. Many proofs of such condensation might be adduced. Lime will take up and solidify water from the air, long after the temperature of the combined hydrate is above that of the lungs; and salt dissolved in water will prevent it from boiling until it reaches 13 or 14 degrees above 212°.

“Numerous examples could be adduced to show that caloric must be generated in some way different from that said to be produced by respiration. Persons have been known to drink ten gallons of cold water during a day, which was soon raised to their own temperature, a difference of 40 or 50 degrees. Dr. Good says, 400 pints of wine and water have in some cases been swallowed daily. In many instances, the expenditure of caloric is far greater than the more common theories would account for.

“But whether we attribute the evolution and uniform preservation of regular animal heat to the junction of oxygen and carbon in the circulation, with Crawford and most of the enlightened modern physiologists—to the meeting and action of these gases in the lungs, with Dr. Black and Lavoisier—to the production of heat from food during nutrition, with Descartes, Franklin, Rigby, and Hunter—to galvanism and nervous influence, with Philip, Brodie, and many others—or to the liberation of 1000 proportionals of heat from the solidification of vapour, when condensing to form hydrates in our solids or fluids, as I have ventured to set forth,—whatever be the source or means which regulate our temperature, whether any, or none of these, or all of them com-

bined, we should remember, that the end of our speculations should be, to ascertain the causes of altered conditions and consequent disorders; and our next aim, to keep in view the great object of arriving at some rational means of altering, alleviating, or removing the untoward changes which have occurred in disease, and superinducing the former healthy state, or one as nearly as possible approximating to that of natural salubrity or healthy disposition."

This chemico-conjectural theory of the formation of animal hydrates seems scarcely to require any very critical remarks of ours upon its merits. We pass on to other topics equally important—more comprehensible—and perhaps quite as well handled by the author. To us, we will confess, one of the strongest recommendations of the volume is its extraordinary variety; we find on turning over its pages the subjects of baths, tea and coffee drinking, and difficult labours discussed, "with a most learned spirit of observation." We perceive the Doctor at one moment engaged in pronouncing on the influence of the *par vagum* in digestion, and the next, exerting himself in the cause of temperance, by denouncing drunkenness, and crying up the practical morality of water drinking. But, seriously, we are much pleased with his views of the application of iodine: he claims the merit of being the first to propose it—we question not his claim; it is a simple and easy application, and in the distressing maladies for which the author declares it to be a most efficacious remedy (if used in reasonable time), we really think it deserving of a fair trial.

"The valuable property possessed by iodine, of subliming where moisture is present, below the temperature of boiling water, and of remaining diffused at low degrees of heat (even that of the atmosphere) when humid, entitles it to attentive consideration as a remedy by inhalation. Add to this its well-known powers in removing serofulous affections and dissipating tumors, rendering the skin more insensible, and pain less acute; giving it claims to minute investigation as a local remedy in complaints of the lungs of a tubercular or serofulous character or disposition, as well as to ulcers in those organs requiring for their cure an altered action or condition."

With regard to its effects generally, the author informs us, that though he sometimes used it in cases where no ultimate hopes of recovery were entertained, yet it contributed even here to procure at least temporary relief; and aided probably by the uniform temperature kept up its diffusion in the apartments, it never failed to lessen the severity of the cough, to promote easy expectoration, to diminish the frequency of the pulse, and whether from possessing some soporific property in vapour, or from the comparative ease afforded, there was evidently observed a greater disposition to repose.

The manner of filling an apartment with the iodine vapour is extremely simple. A cup or opened phial, containing moistened iodine, is suspended in the jet of steam which proceeds from a tube attached to a common boiler. It sublimes in its characteristic violet gaseous form. In summer, a small cup of moistened iodine, set in a bowl of hot water, elevates abundance of the medicine about the bed. A stream of it can be directed by a thin glass pipe over the patient's face, its great specific gravity causing it to fall and be inhaled. An atmosphere of iodine vapour and that of water mixed with air, can, in fact, be regulated to such strength as the patient finds agreeable; and the apartment reminds you, on entering, of the smell arising from kelp kilns burning marine vegetables along the coast.

Some illustrative cases are appended.

Before we conclude our notice of this interesting volume, by the way, we have just read the new mode of performing the operation of bronchotomy (!) recommended by the author, but which our limits preclude—we will extract an amusing account of Dr. Murray's favourite practice in the treatment of scalds. It will be seen that he is partial in this respect at least, to the homœopathic system; for our parts, however, we are much "of the same opinion still," advocates for Mr. Earle's plan.

"Passing one day through Talbot-Street, my attention was arrested by loud screams. On reaching the room of the house from which they issued, I found that a boy had slipped off a chair into a pot of boiling broth, which had just then been set off the fire on the floor. Both legs were immersed for some moments up to the knees. His

mother having extricated him, whether with the instinct of nature or from whatever motive, she plunged one of the limbs into a deep can of cold water: at the moment I entered, the other was just about to be immersed in a similar vessel. The instant of danger is not one for deliberation. I at once laid hold on the scalding leg just dipping into the frigid pail—held it up—threw into the vessel a few ladles of the boiling broth—quickly introduced the limb into this warm mixture, and retained all the scalded part under its surface. Pain was certainly increased by this procedure—the plan was neither congenial to patient nor parent—still I persisted, notwithstanding the murmurs “not loud, but deep,” which the busy bystanders circulated unsparingly around. This was the right leg. The left was kept by the poor mother of the boy in the cold water. She had the satisfaction to hear that her plan was removing all the pain, whilst mine was thought a repetition of the scalding a second time. Here, however, was a case for conviction. Two limbs of the same individual, both equally scalded, immersed the same period of time, and the same height, in boiling broth, were almost accidentally submitted, the one to the cold, the other to the warm mode of management. Setting aside any impressions on the system, I persisted in obtaining topical fair play for the comparison. When the limbs were about an hour immersed, they were folded up in cotton, and the patient was then laid in bed. The right limb was red, and inflamed, and painful; the left paper white, puffy, and insensible. Next day it was evident, even to the prejudiced attendants, that the limb treated by me maintained its circulation throughout its entire surface; whereas that of the left had ceased through all the integuments. My leg and foot, as they were called, were well in a week. The mother’s limb lasted long enough, sloughed, and threw off portions of skin and sphacelated cellular membrane for months. The recovery of course was slow, and the surface scarred with seams and cicatrizations.”

One thing we cannot help noticing as we take our leave of this author—the strange tone of half-apprehension, half-defiance of his critics, which he maintains in his preface, and in many parts of his book. It put us strongly in mind

of Sir Fretful Plagiary’s vein. Whether or not he has equal cause with that worthy knight for his extreme sensitiveness, we will not undertake positively to decide, but we will take leave to say that “it looks very suspicious.”

MEDICAL GAZETTE.

Saturday, June 5, 1830.

“*Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.*”—CICERO.

THE LONDON UNIVERSITY.

THE fate of the London University seems to hang on the medical school, and if we may judge from the extraordinary exertions made to get up this department, the event is not contemplated without anxiety. It is not a little remarkable, that this institution appears to have failed in what was most wanted, and succeeded in that which was not wanted at all. Certain it is that, as a general school, it has lamentably disappointed the hopes of the proprietors, and that the partial success it has met with in one department constitutes but a feeble prop for so extensive a concern. The first circumstance that offers itself in explanation of this result is, that the University has met with least encouragement from those to whom its advantages and disadvantages may be supposed to be best known—namely, the inhabitants of London; for it is notorious that those to whom its halls are most accessible have been least disposed to enter them. Indeed, had the number of students from the metropolis borne any fair proportion to those from the provinces, the event would have been very different. Now the medical profession is the only one regularly taught within the walls of

the University, which requires that the student should visit the capital before his education can be completed, or at least before he can obtain a license to practise as an apothecary, or a diploma in surgery; and it is from the source thus opened that the chief supply of students has been derived. Indeed the number of young gentlemen from the provincial towns, who have terminated their journey in the vicinity of Gower-Street, would seem to shew that the reputation of the University stands higher at a distance than in its more immediate vicinity. In this way, we presume, is to be explained the fact, that, of twenty-seven medals distributed the other day, three only were bestowed upon pupils resident in London.

We have been led to these reflections from witnessing the late distribution of "honours" to the medical pupils; a ceremony well calculated to produce an imposing effect,—the purpose for which it is obviously intended. Sir James Graham presided on this occasion, and did it well. We particularly admired the ingenuity with which he turned his varied compliments to the successful candidates; his concluding address, too, was brief, gentlemanly, and pleasing. Yet was the whole very unlike what our associations are familiar with; it wanted the dignity which gives so impressive a solemnity to the analogous ceremonies of an University of the olden stamp. There was a boyishness too in the kind of "honour," reminding us of the similar medals given at schools to the most deserving scholars, and from which the idea has been rather too closely copied. We went with an undefined persuasion, from what we had heard, that we should see some fortunate candidate presented with an appointment to India, or some equally substantial honour. Neither can we compliment the professors on the figure they made on this occasion; it was such as naturally suggested the

question, whether the pupils had been attracted by the accomplishments of their teachers, or by the "pomp and circumstance" of the situations which they held. There were one or two exceptions to this, it is true; but these only served to render the deficiencies of the others more apparent. Many of the professors, indeed, absented themselves, and there were fewer of the patrons of the institution present than on the corresponding ceremony last year—a circumstance which, we presume, is to be attributed to the dissensions which prevail among them.

In reading the report of the Medical Classes on the day of the ceremony above-mentioned, the Warden took occasion to introduce some extracts from a document lately agreed on by the Council, and which will be found in a former number of the Gazette, (127). It is, in fact, a manifesto of the conditions on which they intend to confer a general certificate of attendance and acquirements, under the imposing title of a diploma. It further announces the important piece of intelligence, that this education is especially designed to suit the *General Practitioner*—and that, to use their own words, "until this University can give a physician's degree," it is opened as the grand emporium for the accommodation of "by far the largest class of the medical profession." The Council, it seems, have taken into consideration the wants of the general practitioner, and most disinterestedly hold it to be "a great duty" to supply them. All this is exceedingly contemptible: the Council of the London University know—or ought to know—that, as a medical school, their institution was wholly uncalled for;—that there were, and are connected with the great hospitals in London, schools at least as good as theirs; and that the "great duty" of providing for the education of surgeons and general practitioners was not left

for them to fulfil. It were more judicious not to provoke too rigid an inquiry into the foundation of those claims on which they would arrogate a superiority which they do not possess, or force a comparison between their professors and the private lecturers in London, among whom are to be found some of the most eminent physicians and surgeons of the metropolis. Besides, granting them to equal the most experienced and successful among our long-established lecturers—and it is granting more than they are entitled to—still would the advantages to be derived from the immediate connexion of precept and example—the constant appeal from theory to practice—which is made, and can only be made, within the walls of an Hospital—turn the balance against the University, in the eyes of those whose object is to acquire an intimate acquaintance with the business of their profession. An Hospital constitutes a living museum of disease; and when this is connected, as at most of these institutions it now is, with abundant opportunities of pathological investigation, it gives to their schools an immeasurable advantage.

As to the rest, if appending a few letters after their names be considered by young gentlemen as an advantage, we would advise the physicians and surgeons connected with the hospital schools forthwith to confer diplomas. We should thus have “Masters of Medicine and Surgery” in the *University* of St. Bartholomew’s—in the United Colleges of Guy and St. Thomas—or, what would come nearer the mark, in the *London University* at Mile-End-Road. Should this system of conferring degrees be carried into effect by private teachers, such as those of the *London University*, it will degrade science, and bring such distinctions into ridicule.

The interests of the College of Physicians and of the Society of Apothe-

caries are pretty well defended by law from the effect of these innovations; not so the College of Surgeons—their diploma is honorary—and we doubt not that the Council of the school in Gower-street had this in mind in contriving their diploma. Some, they have conjectured, will prefer to become “masters” in surgery to any less imposing designation; and if the government should persist in laying a duty of 10*l.* on the diploma of the College of Surgeons, without giving them any equivalent advantage, while they suffer the certificate of the University to pass untaxed, as the deed of a private association, (in which light they regard that institution,) then may the Court of Examiners keep holiday, for their labours, we suspect, will be marvellously light. If the Council value the interests of surgery, let them look to it.

The pages of this journal have been open to the commendations of the *London University*, and a reference to various former articles will shew that we have spoken of it fairly and without prejudice; but when we see a set of gentlemen forming an academy on speculation, which they are pleased to call a *University*—an absurdity to which we long ago drew attention (*Gazette*, 11th October, 1828,)—when, not content with the misnomer, they endeavour to keep up the deception by talking of conferring degrees which they have no more power to bestow than any other joint-stock company—and when they have recourse to puffing advertisements of themselves, and implied depreciation of others, to enhance the value of their property;—then are we reluctantly compelled to express our disapprobation; nor are we free from misgivings as to the stability of a concern which at so early a period of its existence has recourse to so much quackery for its support.

THE KING'S PROFESSIONAL ATTENDANTS.

RATHER more than three years ago, it was very gravely stated in the *Lancet* that Sir Astley Cooper had been sent by the King to visit his Royal Highness the Duke of York, on which occasion he prescribed something which had produced marvellously good effects;—and now we are told that his Majesty is taking the same remedy with “great benefit.” To those acquainted with the manner in which the practice of our profession is conducted, it is almost unnecessary to state that there is not one syllable of truth in this story from beginning to end. Sir A. Cooper *neither prescribed nor suggested any internal remedy* during his attendance on the Duke of York, and was called in solely in consequence of his Royal Highness yielding to the repeated request of Sir Patrick M'Gregor, who did not like that Mr. Simpson and he should have the responsibility of the surgical part of the case after mortification of the legs had come on. The prescription too—which the Editor of the *Lancet* seems to think something extraordinary—by his own shewing, was nothing more than blue pill and squill!! a combination in such common use that it would have been wonderful indeed if it had been left for Sir Astley to suggest it.

It is curious that the observations which we made last week contained an answer, by anticipation, to the article which simultaneously appeared in the *Lancet*, and that the falsehoods this last contained should actually have gone forth to the world in the pages of various newspapers—*preceded* by their refutation. Since then we have referred to the statements which were made public at the time, and find in the leading article of the *Courier* of January 10, 1827, being three or four days after the decease of his Royal Highness, the

following *official* article, which affords a complete confirmation of all that we have said; and which, as the contrary has been again affirmed, we now insert to prove that the remarks in our last number were not made without a sufficient knowledge of the facts.

“After all that has been said and repeated respecting Sir Astley Cooper's attendance upon the late most-lamented Duke of York, it will surprise the generality of our readers to be assured, as we do now assure them, upon the best authority—

1st. That Sir A. Cooper was called in to see his Royal Highness, at the request of Mr. M'Gregor, on the 16th of October, sanctioned by his Royal Highness, to whom that request had been conveyed by Sir H. Taylor.

2d. That Sir A. Cooper, in conjunction with the two other surgeons, Mr. M'Gregor and Mr. Simpson, administered to the external ailments of the royal sufferer.

3d. That Sir A. Cooper never prescribed any internal remedy whatever.

We do not mention these circumstances invidiously, but only to prevent the public from supposing that the physicians could abandon their province of prescribing to one of the surgeons, and from disparaging the zeal and efficiency of all the other medical attendants of his Royal Highness. This would necessarily be the general opinion if it be allowed to go out to the world that the physicians yielded the important lead to an individual who shared in common, not exclusively, the merit of devoting his zealous unremitted attention to the employment of the best means of saving the valuable life of his distinguished patient. We take this opportunity of adding, that no scarification of the legs ever took place, nor was a blister applied.”

While the story remained confined to the pages of the *Lancet*, in which it originally appeared, it was not thought worth while to contradict it; but having afterwards been copied into one of the morning papers, Sir A. Cooper addressed the following note to the Editor:—

Sir,—I appeal to your candour to

contradict the paragraph in your paper of yesterday, (and which was probably copied from some other) respecting the medical treatment of his Royal Highness the Duke of York, as it contains a statement which has no foundation in truth. I am, yours, &c.

ASTLEY COOPER.

Spring Gardens, Jan. 9, 1827.

So much for this absurd story, which is now renewed by its original author, in despite of the contradiction of the party to whom it refers; and for the obvious purpose of derogating from the royal physicians. Sir Astley Cooper, considered as a surgeon, has attained a pre-eminence so high that nothing but the extremity of weakness could induce him to think of aspiring to a reputation for skill in the practice of physic: and we are persuaded he would just as little have thought of attempting to instruct the physicians in the treatment of a medical case, as they to direct him in the performance of a capital operation.

But why has the name of Sir Astley Cooper been thus impertinently dragged forward by our contemporary? Can any one suppose it agreeable or advantageous to him to have his name blazoned forth in newspapers as one towards whom some slight has been shewn? Or can it for a moment be imagined that the Editor of the *Lancet* is thus sore because the distinguished surgeon to whom he alludes has not been sent for? It is notorious, that while the false impression could be kept up that Mr. Brodie was not in attendance on the King, not a syllable was breathed in the *Lancet* either to remove the deception or to censure the proceeding. But when it became too public to be concealed, or *again** to be denied, that his assistance had been required by his Royal master, then did our contemporary, forgetful of the contemptuous and disgraceful manner in which he has been accustomed to speak of Sir Astley

Cooper, forthwith demand why his opinion—the opinion of the “serjeant surgeon”—was not taken? We can answer this:—the same reason which led to Sir Astley Cooper being employed to attend the King when he was not serjeant-surgeon, now leads to the employment of another when he is—the Royal will. During his present illness his Majesty has remained unimpaired in mind, and still is “every inch a King.” Nor can any thing be more absurd than the idea that any “secret” influence, even were it used, could prevent him from exercising a privilege not denied to the meanest of his subjects—that of choosing by whom he shall be attended in the hour of sickness. That he has exercised that privilege, and that his choice fell where it did, is the real cause of the ludicrous tone of disappointment in which the last two or three numbers of the *Lancet* have been penned.

The above details relate to facts which will become matters of history. As to the rest of the article—the demand that the physicians should describe the “symptoms,” and “submit their treatment” to the public, in violation of all propriety, delicacy, and even decency, in order that the Editor of the *Lancet* might be enabled to write comments, and have them copied into the newspapers—this, and a great deal of stuff besides, we pass by, as wholly undeserving of comment. The writer cannot be such a fool as to hope that the members of the medical profession will be blind to his motives or deceived by his hypocrisy.

HOSPITAL REPORTS.

GLASGOW INFIRMARY.

[Concluded from our preceding Number.]

Injuries of the Head.

CASE III.—John Curbans, aged 21, a slater, admitted 8th September, having

* It is not true that Mr. Brodie has been in attendance upon his Majesty.—*Lancet*, May 1.

fallen from a scaffold two stories high on the preceding day, and struck his head in the descent against the edge of a wall. A quantity of slates which came down along with him, fell upon the lower part of his back. He was stunned by the fall, though not rendered altogether insensible, and vomited. There was a wound an inch long through the integuments of the right eyebrow, and another of a triangular shape over the right temple. In this situation the bone was exposed, and the probe could be passed from the wound upwards and backwards, to the extent of three inches.

On admission he had little headache, his chief complaint being a fixed pain at the lower part of the belly, with inability to void urine. The pulse was rather quick. The catheter was used; the edges of the wounds were brought together by means of sticking-plaster; warm fomentations to the belly, and castor oil, were ordered.

The fever, &c. having increased on the following day, he was bled to \mathfrak{xxvi} ., and had twelve leeches applied to the lower part of the belly, after which he felt considerably easier. The bleeding was repeated on the 10th, and the saline mixture ordered. The pain of belly was less, and otherwise he appeared better on the 11th. The discharge from the wounds was rather copious, but not particularly unhealthy. There was a recurrence of pain in the hypogastrium, with increase of fever, on the 12th, when twelve ounces of blood were extracted from the lower part of the back by means of the cupping-glasses. From this date he did not require the use of the catheter.

Up to the morning of the 21st, when he had a rigor, he continued to do remarkably well, the wounds discharging healthy matter, and he being all the while free from any fever. He had an uncomfortable feeling of pain and tightness around the head, the countenance was flushed, the aspect of the sore was pale, and the discharge thin and scanty. Pulse 112. To be bled from the temporal artery, to have a blister to the nape of the neck, a dose of castor oil, and afterwards gr.ii. calomel three times a day. He was immediately relieved by the bleeding, and on the 22d had no pain of head, and every way felt better. The calomel was continued, and the blistered surface ordered to be dressed with resinous ointment.

24th. "Continues to improve. Pulse 80, soft and of good strength; discharge tolerably healthy; mouth not yet affected."

26th. "Mouth sore; discharge good; otherwise feels well." Omit the calomel.

He had a return of rigor on the forenoon of the 27th, though previously was cheerful, and had taken breakfast with relish. Wound over eyebrow nearly healed; that above temple has a pale glazed appearance, and discharges copiously a brown serous fluid. From

this the probe passes nearly four inches backwards, in which situation there is an elastic fluctuating swelling. This was immediately laid open from the posterior angle of the wound, to the distance of two inches and a half, exposing a considerable surface of the bone bare and rough. Two branches of the temporal artery were necessarily divided, and in this way about \mathfrak{xxviii} . of blood were lost, after which he felt the pain of the head much easier. Pulse 116, sharp; countenance flushed; tongue quite clean; mouth nearly free of mercurial taint. He was ordered a dose of physic, and to have a blister applied to the head.

The bleeding was repeated to \mathfrak{xx} . on the 28th, and the use of the calomel recommended every third hour. He passed a good night, and on the following day the pulse had fallen to 92.

30th. "Pain of head gone; otherwise feels easy; pulse 84, calm. Tolerably healthy discharge from wound, which looks clean. Mouth slightly affected. From this date he continued to improve. Ptyalism having taken place, the mercury was finally omitted on the 3d October, after which the gums remained very tender for nearly a fortnight. The pulse kept stationary at 76. Healthy granulations sprung up from the surface of the denuded bone and surrounding soft parts. He was dismissed cured on the 26th October, the wound having been wholly cicatrised for several days previously*."

The preceding is an instance of concussion both of the spine and brain. Although the fall seemed to have been very severe, yet he suffered but momentary stupor, followed by vomiting. Symptoms of cerebral disturbance did not evince themselves till 14 days subsequent to the accident.

These, as also the unfavourable symptoms which took place on the 27th, when he had a relapse, were ushered in, as is usually the case after injuries of the head, by a rigor, with a glazed, unhealthy appearance of the wound. When admitted he was free from fever, the local symptoms being pain at the lower part of the back and in the hypogastrium. There was also retention of urine, with paralysis of the sphincter ani. These subsided after free depletion, both general and local, fomentations, purgatives, and the use of the catheter. Palsy of the bladder is

* This man was requested to live abstemiously, and to return immediately to the hospital in the event of a recurrence of any unfavorable symptom. I have not seen him, but am informed that he has been quite well since.

a common effect of injuries of the back ; but in this instance it seemed to be accompanied by actual inflammation of that organ, or of parts in the immediate vicinity. The treatment at first had recourse to was, doubtless, beneficial in lessening the tendency to inflammation of the brain, having lost during that period upwards of forty ounces of blood, so that he was very much reduced by the time the bad symptoms appeared.

The utility of mercury after blood-letting was well marked in this case. The unpleasant symptoms disappeared almost immediately, on the mouth becoming decidedly under the influence of that medicine. At both relapses venesection was not sufficient to remove the pain, &c. Mercury, therefore, may be considered as one of the best auxiliaries to bleeding in the treatment of such cases. To ensure its full effect, however, I am persuaded that the medicine ought to be carried to the extent of producing smart pytalism, as is so beautifully exemplified in the cure of iritis, and of some of the other disorganising inflammations of the eyeball. In addition to its other effects of exciting absorption, &c. it may not improperly be said to act beneficially, partly, as a counter-irritant.

The opinion was long entertained that a bone, when deprived of its periosteal covering, must necessarily exfoliate. The contrary, as I have often witnessed on other occasions, was seen to take place. The surface of the bone granulated, and in process of cure these granulations readily inoculated with those from the surrounding soft parts.

Several other cases of injury of the head were admitted. The following, however, is in many particulars interesting.

CASE IV.—George M'Donald, aged 40, was admitted 27th February, under the care of my predecessor, Dr. Couper. On the 2d January preceding, when intoxicated, he had fallen down a stair, and pitched on his head. He remained insensible for ten minutes after the accident. With the exception of a slight abrasion of the left cheek, there was elsewhere no mark of injury to be seen. He continued at his employment during the first week. He had then a rigor, was sick and drowsy, and affected with severe shooting pain in the forehead and across the temples. At length a small puffy tumor appeared over the upper part of the left parietal bone. This having

extended, was opened a few days previous to admission, and a quantity of matter discharged. In this situation the bone was found broken into several small pieces, and slightly depressed. The integuments were undermined, and the probe grated on rough bone to the extent of two inches round the opening. There was no paralysis, and he seemed perfectly intelligent. Pulse 80 ; bowels slow. He was bled from the arm, had leeches applied to the head, and was purged, with decided relief. The headache again became severe on the 4th March, when leeches were repeated. He remained in the hospital till the 21st April, during which period he was never free of headache. The treatment had recourse to was the application of leeches and cold lotions to the head, the occasional use of purgatives, and an alterative course of mercury. On his leaving the hospital the following report is entered in the Journal: "Has little pain in the head, and otherwise appears in good health. No portion of the denuded and depressed bone has yet come away."

This person was re-admitted on the 16th May. The headache, which had been more or less constant from the time he left the hospital, was now particularly severe. There was no other bad symptom. He was addicted to dissipated habits, and had been living rather irregularly. The sore on the upper part of the skull was about the size of a sixpence. The surrounding scalp was quite adherent. The depressed bone felt rough, and was covered with flabby granulations. The treatment consisted in the application of blisters, and the use of mercury to pytalism. He left the hospital on the 11th June, still affected with headache, though much less severe. No change had taken place on the sore.

He was again admitted on the 4th July, and in the interval had been living very abstemiously. The pain was constant, and so severe that he could neither walk nor stoop. He complained of loss of memory. A caustic issue was inserted in the nape of the neck ; and the edges of the sore on the head, which were inverted, were pared. Two days subsequent to this erysipelas of the scalp and face took place, preceded by a rigor. Delirium ensued early, and he remained very ill for nearly a week. The affection having subsided, healthy granulations sprung up from the surface of the sore, which speedily cicatrised, no exfoliation of bone taking place. He left the hospital perfectly free of headache on the 9th of August. I have not heard of him since the middle of September, at which date he was well, and able to follow his usual employment—a tanner.

The following case happened in private, but may be here mentioned as a striking exception to what generally takes place in si-

milar injuries. It serves to illustrate the fact, that the presence of matter between the dura mater and skull consequent to an injury, is not always indicated and preceded, as Mr. Pott would lead us to suppose, by the spontaneous separation of the pericranium from the skull, and the formation of the "puffy tumor" of the scalp.

CASE V.—A gentleman, aged 21, in descending a stair, fell forwards, and pitched his head against the wall at the bottom of the stair. He was slightly stunned by the blow, and after a few minutes, rose up and walked home. There was no visible mark of injury on the head. He continued in his usual state of health for nearly a month. At length he became affected with headache, vertigo, and other cephalic symptoms. The pulse was about 40. Stupor and convulsions ensued, and he died apoplectic seven weeks from the receipt of the accident.

Inspection.—On reflecting the scalp and pericranium, which were every where firmly adherent to the skull, two fissured fractures were discovered on the upper part of the left parietal bone. These were situated an inch apart, and ran parallel to each other, in an oblique direction towards the sagittal suture, where they terminated. The dura mater underneath was separated from the bone, which was rough to the extent of three square inches. This space was occupied by dark-coloured sanies, with a sloughy state of the outer layer of the dura mater. The inner surface of this membrane was of its natural smoothness and colour. The brain, particularly the cerebellum, was unusually soft.

NOTE FROM DR. MOTT.

To the Editor of the London Medical Gazette.

New York, 25, Park-Place,
April 30, 1830.

SIR,

In publishing the case of immobility of the jaw, with a drawing of the instrument used for opening the mouth, my only wish was to make known to others an instrument which I had found useful, and particularly adapted to such cases; but I did not anticipate the effect it has produced on your Bath correspondent.

The invention of the instrument used by me was elicited by the case I had to treat, and could not be influenced by any original in the possession of another person, with whom it remained unnoticed, though it may have been invented for centuries.

It is a little amusing that this instrument, thought to be unique, should have produced

its counterpart, and a claim to originality at so distant a period.

Yours, very respectfully,
VALENTINE MOTT.

ROYAL WESTMINSTER OPHTHALMIC HOSPITAL.

ON Monday last a numerous meeting of the subscribers to this charity was held at the Thatched-House Tavern, to take measures for building a new hospital.

The Duke of Richmond was in the Chair. Lord Grantham, Lord Beresford, Mr. Byng, and Col. Wood, M.P., with many other persons of distinction, took an active part in the resolutions passed.

The principal one was to empower the building committee to proceed forthwith to the erection of a new hospital on the ground granted by the Commissioners of Woods and Forests, near Charing-Cross, in Chandos Street. Plans for the hospital were shewn, and the various views of the building committee very clearly explained by Lord Grantham. It is intended to contain thirty beds for in patients, and it is calculated will cost 5000l.

By a report which was laid on the table, it appears that, during the last year, 1624 persons, all ages, have been admitted to the benefits of the charity, making a total of 16,895 since its institution; of these 550 have been restored to sight by the different operations for cataract.

As forming a valuable school for the treatment of a class of diseases which until of late years was almost exclusively confined to a few oculists, the knowledge of which is nevertheless so important to every medical practitioner, we wish it every success. It is undoubtedly an institution which confers great benefits, not only on the poorer classes but on all, by the opportunities for instruction which it affords. They have yet 2500l. to make up to complete the building fund, and we trust it will not be long before they succeed.

Mr. Jewel has been elected Surgeon-Accoucheur to the St. George's and St. James's Dispensary.

LECTURES ON SURGERY,

Delivered at St. Bartholomew's Hospital,

By WILLIAM LAWRENCE, F.R.S.

LECTURE XLIX.

*Fractures of the Ossa Nasi and Lower Jaw—
of the Vertebra—of the Sternum—of the
Ribs—of the Pelvis.*

GENTLEMEN,—Although the exposed situation of the *ossa-nasi*, and the thinness of the lateral prominent parts, might lead you to suppose that they would frequently be broken, the accident is by no means common, and the little which can be contributed by surgery towards replacing and retaining a fracture of the nasal bones is so obvious, that I need not make any further remark upon the subject.

The form and position of the *lower jaw*, and the circumstance of its being covered by little except integument in the greatest part of its extent, renders it very liable to fracture. The lower jaw may be broken either at the anterior arched portion or in its ascending branches, or at the processes in which these rami, as they are technically called, terminate. The rami of the bone are less strong and considerably thinner than the arched part, but they are covered by a powerful muscle, so that fractures of the rami are comparatively rare. The bone is most frequently broken at the strongest, that is, the anterior arched portion.

Fractures of this part may be either *perpendicular* or *oblique*, and they are said sometimes to be *longitudinal*, but I fancy that must be a very rare occurrence. The bone may be broken at one place, or at more places than one; there may be simple fracture, or the fracture may be complicated with an external wound—that is, there may be com-

pound fracture. The fracture too is often attended with a good deal of contusion, ecchymosis, and swelling of the neighbouring soft parts.

The replacement of a broken lower jaw is very easy. By introducing one or both thumbs into the mouth, and by depressing or carrying backwards the posterior part of the bone, at the same time that we elevate or bring forward the anterior part with the fingers, we can in injuries of this kind replace the parts with great facility. The maintaining it in its situation, and the preventing it from moving, are points not quite so easily accomplished, for we can only apply the means of retention on the external surface of the lower margin of the bone; the whole of the inside is removed from our reach, and it is hardly possible for us to make use of any means applied in that situation to assist in retaining the bone in its place. However, this inconvenience is remedied by another advantage, which is, the immediate and firm support which the lower jaw receives from the upper one when the mouth is closed; and the lower being firmly maintained in apposition to the upper jaw, it may be said that under such circumstances it supplies in some degree the place of a splint. The best, and at the same time the easiest mode of retaining a fractured lower jaw in its place, is the four-tailed bandage, which consists merely of an oblong piece of linen, each end of which is split so as to make two ends, or as they are called, *tails*; then the middle or undivided portion is applied to the chin, and so arranged as to embrace the anterior prominent part of the bone, and the two anterior ends are then carried backwards and fastened behind the head, in the way that I now put it on.—[Mr. Lawrence here placed the bandage on himself.] The posterior ends are brought up along the sides of the ears, and fastened over the top of the head, in this way. Thus you can apply force in a circular direction to the anterior arched portion of the bone, at the same time

that you apply force in a perpendicular direction to the base of the bone below. By the combination of these two forces you maintain the bone in apposition to the upper jaw. The bone of course remains steadily fixed only so long as the person keeps the mouth shut; and in order to avoid the displacement which the natural motions of the jaw in mastication, &c. would produce, persons must abstain from talking, and also from chewing food; they must take merely soft food—spoon-victuals, as they are commonly called, until the union of the bone is effected. It has been sometimes found advantageous to do something more than merely apply this four-tailed bandage to the bone—to make at the time something which serves as a sort of splint; that is, you take a piece of pasteboard, dip it in water, so as to make it quite soft, and cut out a piece that will adapt itself to the inferior edge of the bone. Just make a few snips in it, so that it may sit neatly, and in its moistened state bind it on the jaw with a bandage of this kind. When the pasteboard dries it comes off as a case, exactly accommodated to the part. But you will recollect that pasteboard is a roughish kind of substance, and if it be bound firmly on the tender skin of the face, it will irritate and excoriate it. It will be expedient, therefore, to protect the surface of the parts on which the pasteboard is applied, by covering them with soap cerate, or lining the inside of the pasteboard with linen or with soft rag. By neglecting this precaution, and by binding a piece of rough pasteboard firmly on the jaw, I have frequently seen considerable irritation produced—even inflammation and formation of matter have been the consequences.

It happens, indeed, sometimes, from the violence that has been employed, that the fracture extends to the inside of the mouth, to the part where the jaw is covered by the gum, and thus forms a sort of compound fracture, although there is no external opening in the skin. It sometimes happens that a good deal of inflammatory swelling supervenes in this case, and the occurrence of a considerable abscess is by no means unfrequent. Under such circumstances we must make an opening tolerably early, in order to give exit to the matter. It has been recommended to assist the means you employ for retaining the fragments of the jaw together by tying the teeth on each side of the fissure with silk or wire; however, I believe it does not often happen that these means tend to assist the union.

But while describing this accident, I observe that I have omitted to mention the circumstances to you which indicate its existence—the *symptoms*. Now these, in truth, in consequence of the superficial situation of the bone, are very obvious. In the first

place, if there be any displacement of the broken bone, there is an alteration in the appearance of the lower part of the face; the mouth is a little deformed—it appears to be turned aside—it has not its regular conformation; but when you come to examine the row of teeth on the inside of the mouth, you immediately perceive the irregularity that is produced by the fracture; and by passing the hand along the base of the bone externally, you also become sensible of this. Then further—if you take the two portions of the fracture, one in each hand, you can move the bone, and indeed you hear distinctly a crepitus or grating, caused by the broken ends rubbing against each other. This criterion is so very palpable in the case of fracture of the jaw, that it is hardly possible to make any mistake in judging of the nature of the accident. If the bone be broken at the rami or processes, these parts being covered by the thick masseter muscle, it is by no means so easy for us to be satisfied of the existence of fracture. Little, however, can be done under such circumstances for keeping the parts together—you can merely, as in other cases, bind the lower jaw against the upper one, and enjoin quietude till the fracture be consolidated.

Fractures of the Spine.

The *vertebræ* are not much exposed to fracture, considered *individually*. Their form, their situation, and the way in which they are surrounded by muscles and other soft parts, render it very difficult to have a force applied in such a way as to act particularly on one vertebra without affecting the contiguous ones; fractures, therefore, of the individual bones are rare, though the vertebral column, taken collectively, is liable to fracture—that is, the fracture may pass through the column. In such a case, generally more than one vertebra is involved in the mischief. The body of one vertebra, with the articulating or transverse processes—either of the vertebra above or below—frequently are involved in the case called a fracture of the spine. It is true that both the spinous processes may be broken, or you may have fracture of one of the spinous processes only; this, however, does not take place by any means commonly, for these processes are so covered and enclosed by muscles, that it is difficult to have a force sufficiently powerful to break them applied entirely to one process and to no more. Fracture of the vertebral column generally happens in consequence of the application of some very great degree of force to the body: a person falls from a great height, as from the top of a building, to the ground; or some very heavy weight falls from a height upon the trunk. Now when the column is broken through, the accident may be attended with displacement of the fractured parts, or it may

not. If the fractured parts have undergone displacement, an irregularity may be perceived in the line of the spinous processes, and therefore when you pass your finger along them, you find an interruption in the series of processes—one or more may seem to be depressed or pushed in; or the spine may form an angle at one point, so that one or more parts may project; and this circumstance points out the precise situation where the injury has been received. Frequently, however, though displacement is produced at the time the accident takes place, yet when the force no longer acts upon the spine, it recovers its straight position, and you are not sensible of any inequality in the line of the processes, so that there is no external visible circumstance which will point out the precise spot where the injury has taken place. You can only judge of it by the sensation which the patient describes; but the accident is usually attended with so much pain, just in the situation, that he generally points pretty accurately to the injury. When the column has been displaced, either at the time of the accident or afterwards, it is attended with pressure of the spinal cord, and this pressure produces insensibility and paralysis of all the parts that are seated below the injury. It is this circumstance that renders fracture of the spine so very serious—that renders it, in fact, in general extremely dangerous, and almost necessarily, sooner or later, fatal. A fracture embracing one or more of the vertebrae would be capable of uniting just as well as fracture situated in any other bone of the body, if nothing were concerned except the broken bone; this accident would not be at all more important than a fracture of either of the extremities, but for the great importance of the effects on the spinal cord; and the situation of the cord in the vertebral column is such, that it cannot possibly escape the effects of the injury which I have now described. Even if the spinal cord be not actually pressed upon, the accident will most likely produce the effusion of fluid, or the irritation will occasion so much disturbance in the situation of the spinal cord where the injury has taken place, as to produce effects almost equally serious, though coming on at a remote period. In the great majority of instances, however, the spinal cord receives at the very time of the accident so much injury, as to produce complete paralysis of all the parts that are situated below the seat of injury: these parts are so completely deprived of sensation, that if you pinch or cut the skin, or apply heat to the surface of the body, the patient is not sensible of it; and there is also complete loss of voluntary motion—the patient is not able by his will to influence any muscle receiving nerves from the branches that come from the spinal cord below the injured part. The limbs, there-

fore, and other parts seated below, are totally motionless, and complete insensibility and paralysis are the consequences of this injury. At the same time, the internal organic motions of the part which are necessary for continuing vitality go on—the circulation in the part and the secretions continue—the internal organic life is continued, although the external life, that which consists of sensation and voluntary motion, is put a stop to. The heat of the part is kept up to a certain extent, but not to the same degree as under ordinary circumstances.

This want of power extends itself also to the muscles which belong to the termination of the large intestines, and to the bladder;—the patient has not the power of expelling his urine, which therefore must be drawn off by a catheter;—the muscles of the large intestines lose their power, so that the fæces pass off involuntarily. The distention of the bladder, and the necessity for using the catheter, exist in the early period of the accident; but after a certain length of time the water runs off involuntarily. There is a singular symptom attending the fracture of the spine, the exact cause of which is not found out, or I am not aware of it—that is, a permanent erection of the penis—a state of priapism. I have seen it occur in whatever situation the fracture of the spine has taken place.

Now the *prognosis*, the chance which the patient has of recovering from the accident, and the length of time that life may last after its occurrence, are circumstances that depend materially on the situation in which the injury has been received. In a fracture of this kind taking place in the first, second, or third vertebra of the neck, if it be attended by displacement of any of the broken parts, so as to cause pressure upon the medulla spinalis, it is immediately fatal, because the pressure takes place above the origin of the phrenic nerve, and respiration, therefore, cannot be continued. When the fracture takes place below the three cervical vertebrae, although the occurrence of fracture in that situation paralyzes the intercostal and abdominal muscles, that is, although it paralyzes the greater portion of the muscles that are involved in the act of respiration, still the phrenic nerve is not involved, and for a certain time respiration is carried on by means of the diaphragm. Fracture of the first, second, or third vertebra, is not necessarily fatal; it is only so under circumstances in which it is attended with such displacement as to produce the pressure that I have just alluded to, and then death is the immediate consequence.—[Mr. Lawrence here presented a preparation, and remarked that there appeared to have been a fracture of the first vertebra of the neck—the atlas. There was a fissure running through that part, yet the individual in whom

the accident took place recovered from it; for the atlas and dentatus were completely ankylosed — soldered together by bony union. There the fracture was not attended with any displacement or pressure.]

A case is mentioned by Sir Astley Cooper, in his work on Fractures and Dislocations, in which a boy, three years of age, received an injury about the upper part of the neck, and after this occurrence he was observed not to be able to move the head without holding it with his hands, that is, the head shook, and he took it in his hands to prevent it from doing so. He died at the end of twelve months, but it did not appear from what cause. It was found on examination that the atlas was broken through, so as to detach the ligament which holds the vertebra dentata in its place.

In fracture of the fourth cervical vertebra, or any inferior one down to the beginning of the dorsal, the patient generally will live from 3 or 4, to 7, 8, or 10 days, according as the fracture is situated higher up or lower down. In such a case, the patient performs respiration simply by means of the diaphragm. The power of contraction of the diaphragm is retained; and when the diaphragm contracts, the abdominal viscera are protruded, so that the chest is enlarged on each inspiration, while expiration seems to result from the reaction of the parts; but respiration, you observe, is performed very imperfectly when confined to this mode. We therefore find that the patients speak in a low tone, and they are incapable of coughing or sneezing; they cannot make an effort for passing the feces or urine; they cannot put the abdominal muscles into action;—in this state life will not long be supported.

I had a case some time ago under my care where the fourth vertebra was dislocated from the fifth, and I may remark respecting such an accident, that dislocation is not to be distinguished from fracture. The patient lived four days. And not long after that period, I had another case in the hospital where the injury was received quite in the lower part of the neck; in fact, the body of the sixth cervical vertebra, with the articulating processes of the vertebra above it, had been fractured, and the body of the sixth vertebra was displaced forward so as to overlap the seventh, and press upon the spinal cord: in that case the patient lived ten days. Patients do not usually survive so long as that after an accident has occurred in the neck.

When the dorsal region of the spine is fractured, the patient will, perhaps, live a fortnight or three weeks. In case of fracture occurring in the lumbar region, the patient may live three, four, five, or six weeks, and in some instances life has been prolonged to a much later period. If I do not mistake, Sir Astley Cooper mentions one instance

where a gentleman survived such an accident nine months.

There is a curious specimen in the College of Surgeons, which was sent by Mr. Harrold, of Cheshunt, where the fracture took place in the spine, just at the commencement of the loins; I think it was the last dorsal or first lumbar that was broken. This patient was kept perfectly at rest; the urine was drawn off for a little time, and after that he recovered a kind of power of expelling the urine himself, which appeared to be effected rather by the action of the abdominal muscles, than by the contractile power of the bladder. However, at the end of six months, he had recovered so considerably that he could sit up in bed, and could nearly dress himself. Although he had still a total want of voluntary power in the lower extremities, he nevertheless had the power of shoving himself down stairs by a step at a time. He died at the end of twelve months. There is a complete bony union—a perfect callus enveloping the body of the vertebra, soldering the pieces together, and what is a singular circumstance in this case, part of the body of one vertebra had been broken off, and driven across the vertebral canal, so as to divide the medulla spinalis completely, the ends being about an inch apart in the preparation. This which I now exhibit is a specimen of fracture of one of the dorsal vertebrae, in which a similar circumstance has taken place. A piece of the body of the bone is broken off, and driven across the column so as to divide the medulla spinalis: this case, then, and that in the museum of the College of Surgeons, shew that a fracture of the spine may recover so far as the fracture goes, and that the vertebrae possess the same power of restoration as exists in other parts of the body.

A gentleman shewed me a curious specimen a few days ago, and asked me what I thought of it: it was a part of the spine, and I said that if I were to give my opinion from merely looking at it, I should say that the spine had been broken, and had been consolidated by bony union; for it had the appearance of having been broken through, and then united;—a formation like rough plastering had taken place at the site of the fracture. He said it had been an injury of the spine. In this instance there was a mass of bone filling up the vertebral canal, and I could hardly see any space in which the medulla spinalis could have remained. He said that it was an instance in which the spinal cord had been completely divided at the situation of the accident, and in fact the present state of the bone shews that it must have been so, for there is not room to pass more than a blowpipe at the situation of the injury. If I do not mistake, the gentleman said, that the patient had recovered so as to walk about; however, it was a complete spe-

cimen of recovery so far as the consolidation of the bone went. There is also a case minutely described by Semmering of a fracture occurring in the lumbar region of the spine, where the patient died six months afterwards from mortification of the lower extremities. The injury occurred here in the first of the lumbar vertebræ, and the articulating processes of the last dorsal were also broken through. Here too there had been a kind of rough substance thrown out, and the fracture had become firmly consolidated.

The next question then is—What treatment should we adopt in these cases? In fracture without any displacement, and where it should seem there is no actual pressure upon the spinal cord, but where the cord, soon after the accident, seems to suffer from inflammation—that is, when pain comes on in the situation of the injury, and extends along the course of the nerves which proceed from the cord below the accident, with convulsions and spasms of limbs (for these are the kind of symptoms that occur in consequence of inflammation affecting the spinal cord), we can only have recourse to antiphlogistic treatment. You must take blood locally, adopt other antiphlogistic means, and enjoin absolute rest. With respect, however, to the ordinary run of cases, where we have paralysis and insensibility immediately attending the accident, we must place the patient in a state of perfect quietude, and keep him absolutely at rest. For this purpose the mechanical beds, invented by Mr. Earle and Mr. Amesbury, are particularly well calculated; because you can place the patient in a position which affords the means of relieving himself without any motion of the body: so that there will be no motion of the broken bones against each other.—none of those movements which may be likely to produce pressure on the spinal cord, or that will be likely to produce or aggravate inflammation or irritation in the same situation. Absolute quietude, therefore, is an essential part in the treatment of these cases; indeed it is the most essential circumstance. You may find it necessary to adopt local means of an antiphlogistic character; and these cases do not in general require other means of that kind. You must employ the catheter, so as to draw off the water at proper times, and then, under favourable circumstances, we see that nature is capable of repairing an injury of this sort, so far as the bones are concerned; though want of power in the limbs of course must be expected to remain, when the spinal cord has received serious injury.

A proposal has been suggested for the relief of the spinal cord from pressure in these cases, by denuding the vertebral column in its posterior aspect, and cutting away, with a saw or a trephine, the spinal process corresponding to the situation in

which the cord may be supposed to suffer, under the idea of relieving it by elevating the depressed bone, or taking away at least that part which causes the pressure, in the same way that we relieve the brain from pressure occasioned by a depression of the bone in fracture of the skull.

The great objection to this proceeding is the uncertainty respecting the precise seat of injury and the precise mode in which the spinal cord has been injured, or continues to suffer pressure. I have mentioned to you already, that sometimes there is an irregularity—an obvious prominence of the spinal processes, which may point out the situation in which you may suppose the injury to have been received, and which might lead you to suppose it probable that an incision might be carried, in order to accomplish the purpose that I have just mentioned. But in a great number of instances there is no direction of that kind to guide you, and you will proceed under a considerable degree of uncertainty whether it might be one or another or a third of the spinous processes that ought to be removed. Then you do not know whether the paralysis is the consequence of pressure existing at the time that you proceed to the operation, or whether it is the result of injury which the spinal cord received at the time of the accident, although it may no longer continue to suffer pressure. Now in the case that I have mentioned to you of fracture, with displacement of a large portion of the cervical column, when we came to examine the patient there was no pressure on the spinal cord at the situation of the accident; but, on cutting open the theca vertebralis, there was observed a softened state of the cord, which rendered it pretty clear that considerable pressure had existed before. Although at the time we made the opening there was no pressure, yet paralysis and loss of sensation were permanent. Now, if you had cut down and trephined the vertebral column in that case, it would be of no service to the patient; and I am convinced that, in a great number of instances, such is the nature of the injury which produces the insensibility and want of motion;—that it is an injury received at the time of the accident—a bruise, contusion, or some injury of that kind—and not merely pressure continuing up to the time when the examination is made. Then again, I have adverted, in the description I have given you, to a case where a part of the bone was broken off from the body of the vertebra and driven across the canal, filling it up; so that removing the spinal process in that case would have been of no kind of advantage to the patient. On the one hand, then, the objection to the operation I have just mentioned, arises from the great uncertainty as to the exact situation or the exact nature of the mischief; and on the other hand, I must ob-

serve, that this operation of exposing and taking away a spinous process or two, is really a very serious and difficult one. Any person who has taken out a part of the vertebrae, even in the dead body, knows that it is no trifling task, though we do not think of performing the operation with the degree of nicety that is requisite in the living subject. It is a kind of operation where, if the vertebral canal were previously uninjured, I should think likely to bring on inflammation of the spinal cord; it would be likely to produce mischief even when there had been no injury before. For these various reasons it seems to me, that the proposal of taking out the spinous processes, in order to relieve the spinal cord from pressure, is one that ought not to be entertained. It has been done in one or two instances, but these cases present no encouragement to a repetition of the attempt.

Fracture of the Sternum.

The sternum is not very frequently broken. Although it presents a pretty broad surface, and considerable violence is frequently offered to it in the shape of blows—although it is not much covered by other parts that tend to avert these injuries—yet, in consequence in a great measure of the elasticity of the cartilages of the ribs with which it is connected, the parts altogether give way, the parieties of the chest yield, consequently the bone very frequently escapes fracture from the kind of violence that you might think capable of producing it. But the sternum is occasionally broken, and the fracture may be a very serious occurrence, or one by no means very important. A very violent injury, such as a wheel passing over the body, will produce it; but then the accident becomes serious, not so much in consequence of the injury which the sternum has received, as in consequence of the violence offered to the parts within the chest. A fracture of the sternum not attended with any of this kind of injury to the internal parts, is by no means a serious occurrence.

A young fellow, about 28 years of age, was brought to St. Bartholomew's Hospital in January 1826, and came under my care. I believe he had been engaged with some of his companions in some sports of a rough nature, and in the course of these his chest had been struck with great violence against the edge of a table. Upon examining him, when he came here, it was evident that the sternum was broken across, about the middle. There was not any displacement, but there was a little irregularity, just enough to indicate the situation of the fracture. He felt a severe pain across that part of the chest, pain which was aggravated on the motion of the parts in breathing and coughing. At the time he came to the hospital his pulse was feeble, and he seemed to be labouring under consi-

derable depression, like a person who had met with an accident of a serious kind. There was a slight motion of the fracture at the situation where it had occurred when he drew his breath in, and when he coughed, or when he made an attempt to elevate the head, a crepitus could be distinctly perceived. Soon after he came to the hospital his pulse recovered, and it was thought fit to take some blood from the arm: he lost twenty ounces with apparent benefit. He had a broad bandage buckled on the chest, similar to that used for a fracture of the ribs. In the course of the night he suffered much from coughing, which produced much pain of the chest in the situation of the fracture. For this a linctus was given, consisting of syrup of poppies and oxymel of squills, and then the case went on without any unfavourable symptoms. He came in on the 16th of January, on the 23d he was able to get up, and on the 2d of February he left the hospital. He got well more quickly than patients usually do from a fracture of the ribs.

I have seen several instances of fracture of the sternum similar to this. It is possible that one end of the fracture may be depressed, but I believe this does not ordinarily happen. The way in which the cartilages of the ribs are connected with the sternum prevents depression. If, however, the inferior fragment of the sternum should be depressed under the superior one, inasmuch as the anterior mediastinum behind it contains only loose membrane, this displacement would not, I apprehend, be important.

Fracture of the Ribs.

Fracture of the Ribs is much more common than that of the sternum. When this takes place on the anterior part or side of the chest, the accident is generally pretty easily recognizable by putting the hand on the part where the violence has been received, or where the patient is sensible of the pain. The movements of the chest produce a sensible crepitus, and the pain which the patient experiences pretty accurately defines the spot where the fracture has taken place. When a fracture is situated in the lower ribs, and rather far back, where the ribs are covered by the muscles of the back, we often do not succeed in detecting grating or crepitus, although all the other circumstances are present that lead us to believe that fracture of the ribs has occurred. In that case, it is best to adopt the treatment that is suitable to fracture. The function of respiration is of course much affected when fracture of the ribs has taken place; for this continued action being attended regularly with more or less of motion of the ribs, a constant source of pain arises; this, however, in some measure, can be avoided, by the diaphragm and the abdominal muscles being employed in

respiration, to the exclusion of the intercostal muscles and the motion of the ribs. If the chest could be kept perfectly at rest—if the patient did not employ the intercostal muscles at all, there would be no moving of the fractured ends of the bone against each other, and no pain experienced. We endeavour to accomplish this purpose as well as we can, by covering the part either by a broad circular bandage of calico or flannel, or by including it in a broad piece of girth, fastened by buckles and straps, which is called a *fractured rib bandage*. Patients very often experience much comfort from the application of a bandage—they find that they can move, or even cough, and breathe freely when it is on, although there is considerable pain from the grating of the broken ends when the bandage is not applied. But in other instances the application of the bandage seems to act unfavourably on the broken ends of the bone, and aggravates the sufferings of the patient, particularly when several ribs are broken; so that under those circumstances we find it necessary to leave the chest without this external pressure. These cases, then, must be regulated by the effect produced. When we see this effect produced by the application of the bandage, we must leave the patient to be guided by his own feelings, and must allow him to tighten the bandage as he pleases, and not have it applied at all if he feels his sufferings to be aggravated by it. If the patient has much cough in consequence of the accident, and if he be of a full habit, it is expedient to bleed and purge him, and to put him on low diet, and then in the course of a fortnight or three weeks he gets quite well. The fracture of a *single rib* is not by any means an important occurrence—the patient recovers easily from it; but when several ribs are broken, the case may be very serious.

There is one particular circumstance connected with the fracture of the ribs, which is very often a source of serious danger—that is, the circumstance of the broken end of the bone wounding the pleura, projecting into the cavity of the chest, and reaching the lungs. Under such circumstances air escapes from the wound of the lung into the cavity of the chest, and very often passes through the opening which the broken bone has made into the cellular membrane in the situation of the fracture. From the freedom of communication of the cellular texture all over the body, the air, when it is once admitted, readily extends over the chest; and, in fact, it may occupy the cellular membrane of the whole of the body, constituting the case termed *emphysema*, in which the cellular membrane is distended with air, as the cells of it are distended with water in the case of anasarca or general dropsy.

The mere distention of the external cel-

lular membrane, although it may produce great swelling, although it may swell the face, and close up the eyes, although it may distort the features so as to render the person hardly distinguishable to those that know him, and although it may swell other parts very considerably—yet this mere distention of the cellular membrane by air is not a thing of great importance.

If the swelling proceeds to any considerable extent in any part, we can get rid of it at once by making a puncture with a lancet, and letting the air escape. When the further introduction of the air is cut off, the air which is contained in the cellular membrane quickly disappears. But the great mischief arises in the case of emphysema from the air which enters into the cavity of the chest, more particularly if it should not meet with a ready exit in passing from that cavity into the cellular texture of the body. The cases, therefore, of emphysema in which there is the largest swelling, are not the most important. If air escapes from a wound of the lung into the cavity of the chest, and is there retained, in the first place, the lung that has been wounded collapses very much, is much diminished in size, and the place which it formerly occupied in the chest is now occupied by the air effused from the wound; but if the air still continues to pass through the wound of the lung into the chest, it not only fills that side of the chest but pushes the mediastinum, which is a moveable partition, to the opposite side, and prevents that lung also from becoming fully distended, so that the impediment to respiration is very much increased. Respiration is rendered imperfect from the wounded lung being collapsed, and therefore incapacitated for the necessary and usual purposes; and a still further effect is produced by the pressure of the air against the mediastinum and lung on the other side. The mediastinum, you are aware, is a moveable partition, in fact, it is so moveable, that when you lie on the right side, the heart pushes it to that side, so that you will not feel the pulsation in the usual situation. The mediastinum is capable of passing in one direction or another, according to any force that is applied to it; and hence matter, or any fluid contained in one side of the chest, will exercise a considerable pressure upon the parts contained in the opposite side through the mediastinum, and under such circumstances, respiration will become extremely embarrassed. The only course for relief that you can adopt is that which you would take if one side of the chest were similarly distended either with water or with pus, that is, you must make an external opening, and allow the air to escape, by which, at all events, temporary relief is given to the patient; and if the distention returns, you must re-open the wound, and allow the same relief again to be produced. You may

make an opening between the fifth and sixth ribs, towards the anterior part of the chest, if it be the right side that is the seat of mischief, but you open it lower down, and farther back, if it be on the left side, so as to avoid the situation of the pericardium and heart.

Fracture of the Pelvis.

Fracture of the *pelvis* can hardly take place except in consequence of some very great violence, such as a tremendous fall, which shatters the part of the body which comes to the ground; or the passage of a carriage-wheel, or something of that kind, over the lower part of the body, in which case the wound arising from the accident is very serious—is generally attended with the wound of an important vessel, or some internal organ. The mere consideration of the fracture is a matter of minor consequence; indeed, in these cases of fracture we can do very little towards relieving the very serious state in which the patient is placed. If the *os pubis* be fractured, you probably have injury to the urethra, which may require a particular mode of treatment; but we are not able to do much in these cases towards replacing and retaining the fractured parts in apposition. All that we can do in the fracture of the *pelvis*, as in the fracture of the spine, is to place the patient in an easy position; to keep him at rest, and administer to any particular symptoms that may occur in the course of the case. If the *sacrum* be fractured, you have in addition to other symptoms, those of paralysis, affecting the muscles that receive their nerves from that situation. It is possible for the superior and anterior part of the spine of the ilium to be broken off by violence of a certain kind. In such a case we can do little more than lay the patient quiet in bed, and let him remain so. It might be possible, perhaps, to employ compresses or bandages that would, in some measure, conduce towards keeping the fracture in a state of apposition.

OBSERVATIONS

ON THE

ANATOMY, PHYSIOLOGY, AND DISEASES OF THE CRYSTALLINE LENS,

And their Treatment.

By RICHARD MIDDLEMORE,

Assistant-Surgeon to the Birmingham Eye Infirmary.

[Concluded from page 363.]

the *cornea* (instead of the *sclerotica*), at the same distance from its union with the *sclerotica* as in the former case. The point of the instrument should be passed obliquely forward towards the pupil, and so depressed as to puncture the capsule and lens. This is nearly all that can be done; and as the cases for which this operation is selected are, or ought to be, such as merely require the admission of the aqueous humour, or a slight disturbance of the capsule and lens, to ensure absorption, no extensive movement can be requisite.

After the operation of extraction has been performed, there are two important points to be secured—the prevention of severe inflammation, and the union of the corneal flap. To effect the first object, it is right to restrict the patient to a low diet, to exclude all light from the eye, and to keep it moistened with some cooling application. A blister at the back of the neck, and a dose of aperient medicine, is generally useful on the second day after the operation. If the lens has been larger than usual; if the section of the cornea has been small, the iris injured either by the knife or the forcible propulsion of the lens; or if the lens has been removed with difficulty, owing to the formation of some posterior adhesion; inflammation of a severe character, indicated by head-ache, pain of the eye-ball, scalding lachrymation, &c. may arise, demanding active depletion and the free exhibition of calomel and opium. We should, however, be cautious in using mercury prior to the union of the cornea; for, in some instances in which it has been liberally administered soon after the operation, no union has occurred, and in other cases, where union had commenced, the connecting medium has appeared to give way, to become absorbed, and no adhesion has subsequently taken place: nothing, therefore, but the most urgent and imperative necessity can justify the free use of calomel at an early period after the operation of extraction.

To assist the union of the divided cornea, (after having accurately approximated its cut surfaces, and restored, with the spoon-end of the curette, the circularity of the iris, if it has been lost by falling against the section, or from any other cause), we carefully close upon it the eyelids, and place upon them a fold of linen, supported by

Operation of Keratonyxis.—In this operation the needle is passed through

a roller loosely passed around the head. The object of this bandage is to quiet the eye, support the cornea, and keep in apposition its divided surfaces. If no great pain or uneasiness be felt, it will not be necessary to remove this bandage on the following day. In about five days it may be dispensed with altogether, for in that time union may be expected to have taken place. This point, however, must be ascertained before it is discontinued; it is not desirable to maintain pressure upon the eye longer than is absolutely required, on account of the irritation it has a tendency to produce. Should the flap display a disposition to bulge forward, soon after the bandage has been left off, it ought to be reapplied; and if this evidence of imperfect union be shewn in an old person, particular attention should be paid to the diet; every thing nourishing and supporting should be liberally administered, and the power of the constitution fostered by every possible means; for if this be not promptly attended to, the object of the operation must be inevitably frustrated, and the cornea as certainly become staphylomatous. Should a tendency to this latter condition be discovered, a solution of the nitrate of silver should be carefully applied, by the aid of a fine pencil, to the partially organized medium of the flap; or it may be applied in substance, after having been scraped to a very fine point, limiting its use, of course, to the imperfectly organized union subsisting between the cut edges of the cornea. As this condition of things most commonly occurs in old persons, from lack of constitutional vigour, it is most desirable to permit such patients to continue the diet to which they have been habituated—to allow them, in short, the same amount of support after the operation as they have been accustomed to receive before. The iris is sometimes drawn towards the incision, after an operation for extraction; an effect generally resulting from an imperfect section of the cornea, laceration or other injury of the iris during the performance of the operation, or from an unusually large lens, the circumference of which is exceedingly firm and dense. It is not owing, as has been represented, to gravity; for if it were, we should find it taking place most frequently after the lower section, and especially when the opening in the cornea has been unusually

large, which, on the contrary, as far as my observation extends, is one means of preventing it. It appears to me, that whenever the opening through which the lens has to pass is too small, the iris is subjected for a long time to forcible distention and stretching, from its unavailing efforts to escape. To this long-continued pressure I am induced to attribute that loss of tonic power which prevents the iris from regaining its circular form. I have seen cases in which the iris has been partially detached from its ciliary connexion, owing to the violent pressure of a lens, the edge of which has pushed against it, between its floating and its ciliary margin; and it has many times occurred to me to witness an iris, after having sustained this pressure for some time, instantly become prolapsed, permanently prolapsed, on the escape of the lens. Such a state of things cannot be remedied; the iris will not recover its tone or its figure; we must therefore endeavour to limit the extent of the prolapsus by a careful apposition of the cut edges of the cornea and the employment (if it increase) of the solution of the nitrate of silver; resting content, if no greater evil follows such an operation ill performed, than a distorted pupil.

It is always right, however, to remedy the mischief, if possible, at an early period, prior to the formation of adhesions: as soon, therefore, as the operation is concluded, let the iris be replaced with the grooved end of the curette, and, if it be necessary, let out a portion of the vitreous humour, so as to diminish the bulk of the contents of the globe; let the corneal flap be properly adjusted, and a quantity of belladonna cerate be placed upon the eye-brow, and repeated every six hours. If the prolapsus appear to be increased by a spasmodic action of the muscles of the globe, give the patient a dose of opium, and employ every measure calculated to allay irritability. Attention to these directions will afford the iris every chance of recovering its circularity, and place it, at all events, under the most favourable circumstances for any restorative process. If, however, our first efforts have not been successful, no second attempt must be made to remedy the evil; for here, in truth, the remedy, whatever it might be, would be worse than the disease; the iris, having become accustomed to its new figure, having acquired adhe-

sions in its novel situation, would not only sustain great injury, probably extensive laceration by any attempt to dislodge it, but would instantly resume its inactive state as soon as the instrument which supported it in its natural position was withdrawn. To the probable mischief, and certain fruitlessness of this interference, as far as regards the iris, would be added the highly-injurious effects upon the divided edges of the corneæ, effects quite irreparable in very old and feeble subjects, for staphyloma corneæ would almost certainly occur. When the uniting medium gives way, and admits of a prolapsus of the iris, which prolapsus is obviously increased by the pressure of the humours, it is advisable to puncture its most prominent part, and having evacuated the aqueous fluid, to adopt the customary plan for uniting the divided edges of the cornea, and preventing any further prolapsus.

I have alluded to iritis as an effect sometimes consequent on the operation of extraction. Now, if this delicate and important part become inflamed, and the inflammation be not checked by active antiphlogistic treatment, the employment of calomel and opium, counter-irritation, cooling lotions, the local application of belladonna, and other measures adapted to the peculiarities of the case, we may have a closed pupil; the iris may meet in the centre of the pupil, and close the opening through which light is transmitted to the back part of the eye; or an adventitious and opaque membrane may be formed in the situation of the pupil, to which the iris may become adherent. It is right to mention, that if, from the too oblique division of the cornea, or the too abundant deposition of lymph in the place of the incision, a degree of opacity should be produced, of sufficient extent to interfere with vision, a solution of the oxymuriate of mercury should be dropped into the eye every night, to obtain its absorption; or what I have found still more useful, the nitrate of silver ointment, as originally suggested, and used for the cure of purulent ophthalmia, by Mr. Guthrie.

The following includes most of the ill consequences which occasionally follow the operation of extraction: iritis, opaque deposition in the situation of the pupil, closed pupil, adhesion of the iris to the corneal section, union by

broad surfaces, super-abundant deposition around the division of the cornea; partial, or general staphyloma of the cornea, or of the sclerotica, and sloughing of the cornea. These are occasional effects; but if the operation be properly performed in an eye suited to its performance; if the cataract be not unusually large, nor have contracted any morbid adhesions to surrounding parts; if the patient be properly prepared for the operation, and judiciously managed after it, it is not expected that any such consequences will take place, because no parts very susceptible of inflammation have been wounded, no vascular, nor deep-seated texture, with the exception of the iris, has been touched, or in any way injured. But in the posterior operation of solution, we find that almost every important part has been either transfixed or otherwise injured; and, as might be expected, inflammation, in its severest form, often takes place. It is true the opening is small, and is made with a sharp instrument—an instrument forming an incised, not a contused wound; but it is still a serious and important injury when we take into consideration the delicacy, susceptibility, and vascularity of the wounded parts; and on this account is only admissible where extraction could not be performed, or where, if the incision of the cornea were made, the removal of the cataract could not be effected without considerable difficulty, or where the lens and vitreous humour are so firmly united as to be almost incapable of separation; or, lastly, where the wound, if made, would not be likely to heal. After this operation, and that to which I shall next refer, we have to contend with inflammation, to promote absorption, and to secure the patulence of the pupil. To accomplish these objects we must adopt the same general treatment as after extraction, modified, of course, by the extent and peculiarity of the inflammation. Bleed, if the pain be severe; administer mercury, if absorption proceed too slowly; and smear over the eyebrow belladonna cerate, to preserve the size and figure of the pupil, to prevent the iris from acquiring any morbid adhesions. It will not, however, be necessary to make any pressure upon the front of the eye, exclusion of light by a four-stringed bandage and a green shade being alone requisite.

If by the operation of keratonyxis we could command the needle, and move it as effectively and freely as in the posterior operation, the latter would be altogether unnecessary, on account of the greater degree of injury it produces; unfortunately, in keratonyxis the motion of the needle is confined, and that proper comminution of the lens which, in some cases, is absolutely necessary for its absorption, is prevented: this constitutes a fatal objection to its frequent application, and obliges us to have recourse to more painful and harmful operations. The operation of depression, extraction through the sclerotica, and some others, proposed for the removal of cataract, seem to me so obviously bad, that I do not deem it necessary to do more than mention them.

After any operation for the removal of the lens, it is desirable that the patient should be kept in a dark room, that the head should not be too much clothed, and that it should be well raised when lying in bed; smoking should not be allowed, nor any forcible action of the muscles of the face, as by the mastication of hard food, permitted; the patient should not approach very near to a fire, nor in any way rub, or otherwise irritate, the eyes.

The crystalline lens is sometimes converted into an osseous mass of variable volume, being sometimes as large as in a state of death, but more commonly shrivelled and diminished in size: sometimes this change is merely partial; more frequently it affects its whole texture; occasionally its surface is smooth, but more generally craggy and uneven; the capsule too is subject to this kind of alteration, and is changed into a smooth lamina of bone, preserving its original form. A short time since I assisted a gentleman in the removal of an ossified capsule, and on examination of it afterwards, we could discover no reason why it should have caused so much disturbance; it was a smooth layer of bone, having no inequality upon its surface, nor was it at all displaced; yet the sufferings of the patient prior to the operation were exceedingly severe, and disappeared immediately after its performance. This disease would appear to be the product of altered action of the vessels of the part, similar to what takes place in other situations. I have only seen it in ad-

vanced age, and in persons afflicted with gout or rheumatism: it would appear also to furnish an additional argument in favour of the vascularity of the lens.

I have said that when the crystalline humour is converted into an ossific mass, it is generally diminished in size and shrivelled in appearance, less frequently enlarged, and irregular in its figure: the vessels of the lens have secreted bone, the natural structure has been absorbed, and the diminution of size occurs as a consequence of the obliteration of vessels, before a deposit equivalent to its natural volume has taken place, or, in other words, that portion of the lens which remained when the obliteration of vessels from ossific deposition took place, has been absorbed. Now, if the lens be not organized, if it be a mere secretion from the arteries of the capsule, bony deposition, if it occurred at all, must take place upon its exterior surface, forming a covering to its natural structure; but it is unnecessary for me to say that such is not the fact, nor am I aware of any case in which such an appearance has been noticed, nor acquainted with any instance in which the healthy structure of the lens has remained, whilst ossific matter has been secreted in the place of the liquor morgagni, or in which the capsule has been converted into an osseous lamina. Is the pain which I have represented as accompanying this morbid change dependent on the pressure of the nerves, or an increased sensibility of the eye, from concomitant alteration of other parts?

Other kinds of disease affecting this part have been mentioned, founded generally on some singularity of form, colour, and consistence, circumstances which alone are insufficient grounds for such a distinction. I do not know that any malignant diseases to which the eye is subject, have their origin in the lens; on the contrary, I have noticed generally a freedom from them; for instance, I have seen the lens drop from the eye of a patient with fungus hæmatodes, nearly in a transparent state; and on one occasion, the mother of an infant brought me an opaque lens, not otherwise altered, which had fallen from its eye soon after a fungus protruded. Indeed if we consider how feeble are its vital powers—how low its organization, this circumstance can excite no sur-

prise; all malignant diseases betray a partiality for highly vascular and richly organized structures: fungus hæmatodes has its origin in the retina; cancer attacks the breasts when the mammary gland has ceased to secrete milk—the uterus, when its vessels no longer continue to pour forth the menstrual discharge, &c. &c. I do not mean to say that this is invariably the case, but it must be allowed that highly-organized parts are chiefly obnoxious to malignant disease, and *vice versa*.

OBSTETRIC SOCIETY.

To the Editor of the London Medical Gazette.

14, New Broad-Street,
June 1, 1830.

SIR,

I HAVE been instructed to furnish you with a short history of the Obstetric Society from its formation, and therefore send to you the inclosed.

I am, Sir,

Your obedient servant,

FRANCIS H. RAMSBOTHAM,
Hon. Sec.

In consequence of the numerous instances which had occurred within the knowledge of many medical practitioners, of great mischief produced by the indiscriminate practice of midwifery, some gentlemen were induced to form themselves into a society at the end of the year 1825, for the purpose of promoting obstetrical knowledge, and of protecting the public from the injuries to which they were exposed. The obstetric society originally consisted of thirty-one members, and since its establishment no others have been added: it includes the names of most of the present and former physicians and surgeons of the obstetrical institutions, as well as most of the lecturers on midwifery in this metropolis. A subscription of two guineas from each member has been found sufficient to meet all the expenses which it has up to the present time incurred.

As it was the great object of this society to act in unison with the three

medical corporate bodies, and as not one of those bodies acknowledged midwifery as a part either of physic or surgery, by examining candidates on their capability to practise this branch of the profession, the most proper and direct course for the society to pursue was thought to be that of addressing the three corporate bodies, stating to them strongly and broadly the feelings which the society entertained on the subject, and requesting to know whether they were disposed to obviate the causes of the calamities complained of. Provided, however, the constituted medical authorities did not consider themselves invested with sufficient powers—or, possessing those powers, did not feel inclined to exercise them for the public good, the society declared their intention of appealing to the legislature for the accomplishment of that object which would then appear to be attainable by no other means. They suggested at the same time that all the desired advantage might be gained, and the proposed protection of the community would be most easily secured, by each body inquiring for itself, through its own examining board, into the extent of the knowledge of midwifery possessed by each candidate who came before them. This mode of proceeding seemed to the society to offer the fewest obstacles, and be most free from objections, as it would leave the relative situations of the three chartered bodies undisturbed, whilst it would secure to the public the certainty of having qualified practitioners in midwifery as well as in the other departments of the profession.

To this letter, which was dated March 20th, 1826, the apothecaries first replied, and in their answer (bearing date April 4th), they stated that “they were well satisfied of the existence of abuses occasioned by the indiscriminate practice of midwifery, and would be happy if it were in their power to render assistance in promoting the laudable object of the society; but they were of opinion that their act did not give them any authority to superintend and regulate the practice of midwifery; they considered the subject well entitled to parliamentary interference, and stated their willingness to conduct examinations in midwifery provided parliament would commit to them the responsibility.” In the reply of the College of Physicians on June 9th, the grand question was com-

pletely evaded ; it merely consisted of a resolution to the effect that " the College was best satisfied when midwifery was practised by those who had been found on examination before them to be competent to the exercise of the profession at large by their knowledge and acquirements ; that the delivery of women was an art of manual skill, and therefore in the province of surgery ; and that the treatment of the diseases of pregnancy and the puerperal state was a part of the general practice of physic, and as such liable to the inquiry of the censor's board." And in the answer of the College of Surgeons, which was not received till July the 19th, four months after the society's address was presented, the positions laid down by the society were tacitly admitted as true by the expressions, "*that the College were not invested with sufficient power to obviate the evils stated by the society to arise from the want of legislative regulations over the practice of midwifery.*"

The society now felt that its next endeavour might with propriety be directed towards obtaining the interference and powerful aid of government in a cause which so intimately concerned the whole community, and a resolution to the effect of addressing his Majesty's secretary of state for the home department was passed in January 1827. Still, however, being willing to afford to the three corporate bodies another opportunity of co-operating with the society in the settlement of the question, the society resolved to address them once more, apprising them at the same time of their determination to apply for the assistance of government.

The replies of the chartered bodies on that occasion followed each other more speedily ; first, from the Surgeons on February 17th, 1827, who stated " that their College was instituted solely for the purpose of examining and attesting the capability of persons to practise the art and science of surgery ; consequently, being solicitous that those persons who conduct the examinations should be particularly skilled in surgery, the College had excluded from the Court of Examiners those surgeons whose time and attention had been occupied in practising the obstetric and pharmaceutical departments of medicine ; that the Council of their College did not perceive how it could compel even its own members to submit to examination in midwifery ; that no tribunal for examining and at-

testing the capabilities of persons to practise midwifery had yet been instituted ; but that the College *would willingly form a board of examination for the midwifery department of medicine* provided the government of the country deemed it necessary, and would give them the requisite authority for that purpose."

On February 22d the Apothecaries returned an answer, referring the society to their former letter ; and on February 27th the Physicians replied, who declined giving any more explicit answer.

The society then addressed a memorial to Mr. Peel, March 20th, 1827, in which the replies from the three corporate bodies were commented upon ; the great responsibility which attaches to the practitioner in midwifery demonstrated : the necessity that exists for every medical man making himself acquainted with that branch of the profession, and the impossibility of detaching it from the general science of physic and surgery, or of studying it separately, clearly shewn. It was also brought before the notice of the secretary of state that instruction on midwifery and the diseases of women and children at that time constituted no necessary part of the courses of lectures as required for examination on medicine and surgery ; and the object of the memorial was declared to be " to oblige all persons who present themselves for examination before the three corporate bodies, to procure such information on the subject of midwifery as should give them competency to practise it ; and to induce the examiners not to neglect the inquiry into such competency in those who present themselves before them as candidates for admission into their respective bodies." It was urged that the protection sought might be best afforded by the by-laws of the corporate bodies being so altered as to ensure professional instruction and examination in this branch of medical science ; and by the repeal of those other by-laws, or the discontinuance of those customs by which men who have added practical information on midwifery to their other acquirements are excluded from the examining boards. It suggested that the same power which was given by act of parliament to the corporate bodies to prevent unqualified persons practising the other branches of medicine and surgery, should be extended also to midwifery ; and, lastly, it declared that the

members of the society could not allow themselves to be selected for the purpose of forming a *separate board* for the regulation of the practice of midwifery, as such a proceeding would imply a *partial* acquaintance with a profession which they had studied as a *whole*, and which they had practised as a *whole* in common with the other members of the bodies to which they individually belong.

At the same time a communication was made to Mr. Peel that a deputation of the society had been empowered to wait on him for the purpose of elucidating whatever might appear imperfectly explained in the memorial, and the Right Honourable Secretary appointed that those gentlemen should attend him on the fourth day after the receipt of the papers. At this interview Mr. Peel stated he had read over attentively the memorial and correspondence; he approved the intention of the society, admitted the importance of its objects, and promised to refer the memorial to the three corporate bodies, whose subsequent answers to the secretary of state were transmitted to the society in July 1827.

In their official answer the College of Physicians considered the examinations entered into at the College on diseases of women and children, a sufficient test of the candidates' knowledge on those points, and the act of delivery an operation of a surgical nature. Yet the surgeons in their reply, far from agreeing with the latter position, contended that *by admitting practitioners in midwifery* into their council they would "weaken that respect the public now entertains for, and the confidence it now has in that council;" they observed "they had hitherto elected as examiners such surgeons as they believed had, in the early period of their lives, been accustomed to pass their days in hospitals, and their nights in the study of their profession, and not in the avocations of a lying-in chamber. They, however, informed the secretary of state that they had, since the society's first application to them, passed a resolution requiring certificates of attendance on two courses of lectures on midwifery from each candidate for a surgical diploma. The society of Apothecaries, on the other hand, in their reply, "considered the object of the obstetrical society as tending highly to the benefit, welfare, and happiness of the community, and to the

usefulness of the medical profession." They "called the serious attention of the secretary of state to the subject, and expressed a hope that some legislative measure might be devised which would in future afford security to the public that practitioners in midwifery were well educated in that branch of the medical profession, and fully competent to the practice of it." But although perfectly convinced of the propriety and necessity of instituting examinations on this subject, they thought the powers they possessed did not authorise them to undertake such a duty.

The statements brought forward, and arguments used by the three corporate bodies on this occasion, demanded severally the notice of the society; and accordingly a second memorial was laid before Mr. Peel, bearing date March 21st, 1828, in which the society, after disposing of those replies, submitted to his consideration an easy and simple plan for placing the practice of midwifery on a respectable footing, viz. that the Colleges of Physicians and Surgeons should be recommended to annul their respective by-laws, by which the fellows of the former, and the members of the Court of Examiners and Council of the latter College, are precluded from the practice of midwifery, and that they should also be recommended to examine all their candidates on midwifery as well as on the other branches of medicine and surgery; whilst to the society of Apothecaries also authority should be given to institute examinations on midwifery.

In the month of January 1829, the committee of the society was informed by one of its members that he had had an interview with Mr. Peel on the subject of the society's second memorial; in which Mr. Peel entered on the different points suggested to him with the greatest kindness and most deliberate attention; he promised to refer that part of the memorial containing the society's propositions to the corporate bodies for their reconsideration; to see the leading members of the physicians and surgeons colleges on the subject; and having so done, to forward the replies from the medical bodies to the society.

After the lapse of five months, during which time no fresh communication reached the society, the chairman having written to Mr. Peel, requesting to know whether any reply had been forwarded

to him from the Colleges of Physicians or Surgeons, received from that gentleman a note inclosing a paper which had been delivered to him a few days before by the president of the College of Physicians.

In this paper the question was approached, for the first time, with something like earnestness, by the College of Physicians. The president, having briefly adverted to the history, constitution, and objects of the College, said, "they could not repeal their by-laws respecting practitioners in midwifery, but proposed, in the name of the College, that as often as any physician offered himself for examination, preparatory to his license to practise, and declared his intention of adding midwifery to the practice of physic, he should be examined before the censor's board, by some licensed physician at that time practising, or who has practised midwifery, who should be called in as an assessor for the purpose of inquiring into his qualifications in the manual branch of that art." No reply has, up to this time, been received by the society from the College of Surgeons. The Company of Apothecaries, however, in accordance with their declaration made both to the Obstetric Society and Mr. Peel, have evinced a strong desire to forward the views of the Society. The chairman of the examining board of that body called upon the secretary of the society in August last, to inquire how far the society had obtained their objects in regard to the Colleges of Physicians and Surgeons, and in what way the Apothecaries' Company could further assist the society. He said they had resolved to require certificates of attendance on two courses of lectures on midwifery and the diseases of women and children from each candidate. They were still of opinion that their act did not give them the power to examine on midwifery. They would be willing to undertake any duties of examination in midwifery that the legislature might think proper to require of them, but they were all agreed that any such extension of their act must come from the government, on the suggestion of the Obstetric Society, and was not to be considered as solicited and promoted by the Apothecaries' Company.

In consequence of this spontaneous declaration on the part of the Apothecaries' Company, the committee of the

Obstetric Society addressed Mr. Peel once more, calling his attention again to the objects and wishes of the society and to the determination of the corporate bodies; and ventured to request the secretary of state to obtain for them the opinion of the law officers of the crown, as to the power possessed by the College of Surgeons and Apothecaries' Company with regard to examinations in midwifery; in order that, if this opinion should be favourable, the two bodies just mentioned might at once act upon it; but should it prove unfavourable, the society then hoped the Right Hon. Secretary would concede to these two bodies the requisite powers for that purpose, and at the same time sanction the introduction into the House of Commons of a bill rendering it penal for any man to practise midwifery who is not a legally authorized physician, surgeon, or apothecary.

This letter called forth from Mr. Peel, in December 1829, an answer to the effect that, if the Apothecaries' Company were uncertain as to the full extent of the powers which they legally possess, and were desirous of obtaining a legal opinion on the point, he must leave it with the board to exercise their discretion in respect to taking such an opinion; he must decline making a special reference from the home department to the law officers of the crown upon the subject; neither could he undertake the introduction into the House of Commons of a bill, such as was proposed by the society.

An abstract from Mr. Peel's letter was forwarded to the Company of Apothecaries, and a reply from the secretary to the Court of Examiners was received by the society in the beginning of February of this year, enclosing the opinion of the Attorney and Solicitor-General, that the Court of Examiners of the Apothecaries' Company have no power, by the act of parliament, to examine in the art of midwifery, which is in no respect comprised in the act.

At the next meeting of the committee it was resolved, that the chairman of the society should wait upon Mr. Peel, as a deputation from the society, for the purpose of forwarding the objects in view: this resolution was complied with: the conversation was principally directed towards the offers made by the Colleges of Physicians and Surgeons, and the opinion of the Attorney and Solicitor-General, respecting the power

possessed by the Society of Apothecaries under their act, was brought forward.

The society was next called together on the 18th of last month, and it was determined, that the three corporate bodies should be again addressed. It was suggested to the College of Physicians, that the regulation they proposed should be extended to *all* candidates who present themselves for a license at the censors' board, instead of being limited to those only who at the time of their examination might declare their intention to practise midwifery. For it appeared to the society, it might happen that candidates who had no intention to practise midwifery, when they applied for a license, might be inclined, at a future period, to add that branch of practice to the practice of physic; and it seemed but just, that all physicians, who were not precluded by the established rules of the College from practising midwifery, should prove, before competent judges, their fitness for that duty.

To the College of Surgeons, the society expressed their satisfaction at the regulations they have adopted, requiring from their candidates certificates of attendance upon lectures on midwifery, and trusted that they would see the necessity of instituting examinations by their own examining board on this branch of surgical science. And to the Society of Apothecaries they offered their thanks for the attention which their former letters had received from that society, and expressed their desire to render their assistance to them in endeavouring to obtain an act of parliament authorizing the Society of Apothecaries to examine those candidates who came before them, as to their qualifications to practise midwifery. The society now wait for any other communication from the three corporate bodies.

It must be observed, that on the institution of the Obstetric Society, it was resolved, that its objects should embrace the regulation of the practice of midwifery with regard to female as well as male practitioners; but it has been thought right to direct the attention of his Majesty's government *at present* only to those persons, practising midwifery, over whom the medical bodies ought to possess some control; no mention has, therefore, been made as yet of the injuries to which the

poorer classes of the community are exposed from the mismanagement of women imperfectly educated in the duties of their profession.

The society, however, has not been unobservant of such dangers, and is most desirous that some means may hereafter be adopted to correct this grievous abuse.

It is also to be remarked, that the society was originally formed with the sole intention of ensuring the welfare of the public as far as midwifery is concerned; and that at one of their first meetings it was resolved, that when the object of regulating the practice of midwifery shall have been carried into effect, its existence shall become extinct.

HOUR-GLASS CONTRACTION OF THE UTERUS.

To the Editor of the London Medical Gazette.

Eton, 26th May, 1830.

SIR,

IN your journal of last week, I observed a letter from Dr. Holbrook, of Cheltenham, commenting upon my case of spasmodic contraction of the uterus, in which he attempts to persuade the profession that I have been deceived in my view of the case, and that his is the correct one. I was disposed to enter fully into the subject, in the hope of convincing that gentleman, that the error was not on my side; but a communication, which I have just received from Sir John Chapman, will have far more weight than any argument I can advance in its favour, and must tend to convince the minds of all unprejudiced persons on the subject*.

* * * *

I remain, Sir,

Your obedient servant,

WILLIAM MOSS.

To W. Moss, Esq.

DEAR SIR,

HAVING just seen Dr. Holbrook's remarks on your case in the last number of the Medical Gazette, but having neither time nor inclination for contro-

* We have not deemed it necessary to resume the discussion about the case related by Mr. Moss, the rather as Sir J. Chapman enters upon the general question.—E. G.

versy, I think it better to transmit you a copy of the statement made a few months since at one of the meetings of the Windsor and Eton Medical Society, together with the accompanying little diagrams to illustrate the same, which you are perfectly at liberty to make what use of you please; and shall only add, if the obliteration of the os uteri is insisted on in the hour-glass contraction (as it has been called), and was admitted, it might be somewhat difficult to prove my position; but would ask, if this obliteration ever continues in any other case after the expulsion of the fœtus? and whether, upon the introduction of the finger after the child has been separated, you do not immediately and instantly feel the funis between the lips of the os uteri, which a few minutes before, whilst dilated by the body of the child, was entirely obliterated? I therefore cannot conceive why, if an hour-glass contraction ever takes place, it should deprive the os uteri, as I have already stated, of its constant and uniform disposition to contract after the body that dilates it is removed.

I would further ask, whether in all other cases requiring manual assistance, the introduction of the hand does not instantly incite the os uteri to action? Few gentlemen can have been in the practice of midwifery many years without discovering that the action of the finger only on the os uteri, after the expulsion of the child, will and does in a torpid or tired state of the uterus excite its contraction, and promote the expulsion of the placenta.

My deduction, therefore, is, that the hand cannot be introduced into the uterus, after the expulsion of the child, without discovering the os uteri; and that I have never yet met with a case, after thirty years' practice, where I first passed the os uteri, and after getting into the body of the uterus, found a second contraction.

Having given you permission to launch my little bark, I shall leave her to the storms that may assail her, and believe me, dear Sir,

Yours truly,

JOHN CHAPMAN.

Windsor, 25th May.

On the Hour-Glass Contraction of the Uterus as a cause of retained Placenta.

This has been a doctrine taught in the schools for many ages, and is be-

lieved both by the professors and their pupils to be as clearly demonstrable as any other fact or principle in nature, the pupils leaving the schools under constant terror and expectation of encountering this formidable difficulty; any attempt to deny or controvert this position, I am fully aware, will bring down upon me all the vengeance of the schools, with all the ridicule and contempt of their proselytes and pupils. I shall, however, only solicit a patient hearing, and a cool exercise of your reason and common sense in the investigation.

We will, therefore, commence with a case of natural labour, wherein a sudden dilatation of the os uteri has taken place, and an equally sudden expulsion of the child follows, with only one or two pains: now we all know that previous to this expulsion, the os uteri is completely dilated, and lost in one general cavity in the vagina, and you cannot any longer ascertain even its edges.

In any sudden expulsion of the fœtus, in the manner I have mentioned, it is sometimes followed by an equally sudden contraction of the uterus, and the placenta becomes closely embraced without any further pain or contraction taking place, and without the usual descent of the uterus. In common cases, when we make an examination after the expulsion of the child, we find the os uteri lying in the vagina loose, and in a state of collapse, its sides lying together with the funis in the centre: if a little gradual action is made with the finger on the sides of the os uteri, a little contraction or slight pain takes place; in from ten to twenty minutes this increases, and the placenta is brought down, particularly if assisted by pressure on the region of the uterus, or rather by squeezing it with your hand, when it is expelled to the os externum. But, in the former case, the uterus is strongly contracted; and after waiting one, two, or more hours, without pain or any effort at expulsion;—either from hæmorrhage or length of time, you pass your hand into the vagina and find you have entered a large cavity (for you have no contraction of the vagina); and when your arm is introduced nearly to the elbow, you find a thick and close contraction (which has been mistaken for the hour-glass contraction); you dilate it with difficulty, and find a very firm contraction em-

bracing the placenta. Now let us stop here, and investigate the case. In the first place, then, after passing the hand through the os externum, have we met with the os uteri and dilated that, and then got into the cavity evidently the uterus, and met with another contraction precisely like a second os uteri, dilated that, and then come into the second or upper chamber of the uterus? for there are two cavities, with a central contraction, in an hour-glass. I say

no; for your hand has passed through the os externum into a large cavity (the vagina), and your first and only difficulty is one central contraction, in which the termination of its sides may be discovered, thickened and closely contracted, but not continuous into another cavity, as it would be in the hour-glass, but you find the edges of it terminating in this cavity, and that it is nothing more than the os uteri itself. I will try to illustrate this better by a diagram.

Fig. 1.

Fig. 2.

Fig. 3.

Fig. 1.—1 shews the state of the uterus previous to the expulsion of the child, with the os uteri (2) lost in the vagina, being one continuous cavity to the os externum.

Fig. 2.—1 and 3 shew the hour-glass contraction, as it has been supposed to exist, with its central contraction, 2-

4, contracted os uteri; and 5 and 6, os externum and vagina.

Fig. 3 shews the true state of the case. 1, the uterus firmly embracing the placenta in a contracted state, the os uteri also contracted, as at 2, with the vagina, 3, still in a state of dilatation.

In a retained placenta, with the uterus contracted, sometime after the expulsion of the child, the hand is passed up very high, when you meet with a contraction, as at 3, fig. 3, and pass your hand forward into a firmly contracted uterus, and not as in fig. 2. You first meet with a contraction shortly after entering the vagina, 4; and then a second contraction, 2; but, as in fig. 3, 1, 2, 3, 4, clearly explains the nature of the case and its difficulties.

My impressions for many years of the existence of this hour-glass contraction was undoubted, until, of late, I began to consider the case more attentively, and am now convinced I have never yet had a case where I have had to surmount two contractions, as in fig. 2, 2 and 4, which must have been the case if this was not hypothetical; which I am, by subsequent experience, convinced of, and that fig. 3 most clearly demonstrates the case.

I feel assured that all I can say will not be sufficiently convincing, so prejudiced and wedded are we to old and preconceived opinions. I therefore only ask that you will not coolly submit to the tradition of the schools, but patiently and quietly examine for yourselves, divested of prejudice, and then I feel assured our deductions will be the same, and that your only astonishment will hereafter be that you could for one moment have believed in its existence, and that you will find the case to be as stated in Fig. 3, No. 2, and not as in Fig. 2, No. 4 and 2, with two powerful contractions in the hour-glass shape.

To remedy this difficulty when it has taken place, get some one to fix their hand firmly and steadily over the uterus, that, when you introduce your hand, it may not be driven away from you in every direction. You then proceed by slowly dilating the os uteri, and pass your hand to the fundus, where, if the placenta is not found detached, you

may proceed cautiously in its separation; when completed, as you gradually withdraw your hand it will be expelled with it, or you keep your fingers above it, and it will precede your hand.

I have thus far confined myself to facts that, to my judgment, are clear and demonstrable; but if I was disposed to attempt any reasoning *à priori*, I should say that it would be contrary to that wise order of nature—that the uterus should be subject to an action that would be constantly at variance with its important uses; and such capricious action as has been stated might and would be liable to strangle the child, or otherwise arrest its regular expulsion: that the uterus has a longitudinal contraction that will arrest expulsion, is very clear by its action frequently on the body of the child, without its expulsive effort, can both be readily conceived and allowed; but that it should be liable to that sudden and central spasm, or contraction, cannot be so readily believed, and I trust the explanation attempted to be given will, on a closer investigation of the case, without prejudice or its shackles to old opinions, be more readily conceded. I am quite alive to an opposition from both old and young obstetricians; and I would on this, as on all other occasions, recommend and adopt a safer position of thinking for ourselves, and concede our consent only when it is consistent both with reason and experience. For I would ask, what could give the uterus the hour-glass appearance (even if I admitted the central contraction) unless some intervening body was in the lower chamber of the uterus as well as the upper? It would either be in a state of collapse or relaxation, or in a state of close contraction, quite inconsistent with that state of contraction which would exist in the upper chamber for the want of some intervening body.

CASE OF

COMPLETE PROLAPSUS OF AN
IMPREGNATED UTERUS.

By WILLIAM COULSON, ESQ.

Consulting Surgeon to the London Lying-In Hospital,
and Surgeon to the General Dispensary.

MARY ANNE REDBURN, ætat. 22, of a delicate constitution and short stature, applied to me on the 23d of April 1830, for a prolapsus of the womb. The patient stated, that she had been delivered about a year ago of a male child, and that, in a month afterwards, without any assignable cause, the womb descended beyond the external lips, in which state (with very little exception) it had continued up to the present period. At the time of the first descent, in May 1829, the uterus was of the size of an egg; it generally, though not always, returned to its natural situation at night, and descended in the morning. The menses also were regular. At Christmas she ceased to menstruate; all the symptoms of pregnancy occurred, and the uterus returned into its natural situation with much less frequency than before. In fact, for five weeks prior to the patient's coming to me, the uterus had remained, both night and day, completely prolapsed; which circumstance induced her to apply for relief. On examination, I found the whole uterus, which was as large as a cocoa-nut, and not unlike it in shape, protruding beyond the external lips; the base of the tumor being surrounded by the lesser lips, and the vagina doubled on itself. The part was very red and hot, but not tender to the touch; the os uteri, to the extent of an inch around, was ulcerated, and the uterus itself felt as if there was a fœtus in it. The patient experienced a dragging sensation from the loins, and felt occasional pains across the lower part of the abdomen.

Treatment.—I recommended that she should keep constantly on her back, apply emollient applications—as fomentations or light poultices, and the tormentilla wash to the ulceration. In addition, to support the part with a well-adapted bandage; but *no attempt at reduction was made.* Internally, castor oil was exhibited. At the end of a month, by this plan of treatment, the

uterus had returned in a great degree; the os uteri being only visible beyond the external lips.

On Monday, May 24th, the membranes burst, and a good deal of water came away; in the evening, no part of the womb protruded; lingering pains supervened, and continued till five o'clock, A.M. of the following Thursday, when true labour pains came on; and a quarter before six she was delivered without any medical assistance, of a male child. I am informed that it was a foot presentation, and that the child exhibited signs of life for three-quarters of an hour after birth.

At half-past one of the same day (Thursday) I visited the patient, with Mr. Jackson, of Church-Street, Spital-fields, who had seen her the night before. The placenta not having come away, Mr. J., on examination, found it lying in the vagina, and removed it. The uterus was in its natural situation.

Remarks.—There are numerous instances on record of complete prolapsus of the womb, both in the impregnated and the unimpregnated state; but cases like the preceding, in which impregnation occurred at the time when a complete prolapsus existed, are more rare, and shew that the most striking displacement of the organ neither prevents conception and the development of the fœtus, nor materially interferes with the health of the mother. The case also illustrates that, by the treatment pursued, the size of the tumor diminished as the time of labour approached. The following case, taken from vol. xliii. p. 367, of the *Journal de Médecine*, bears on the first of these points.

“Elizabeth Gautier, after being married nine years, became pregnant for the first time. From the age of fifteen she had been subject to a complete descent of the womb, with inversion of the vagina; this occurred when she was menstruating, and was attributed to catching cold during that period. At bed-time she returned the womb into its natural situation, and in the morning it always came down. During her pregnancy the whole of the womb protruded beyond the outer lips, the patient experiencing no other inconvenience than a difficulty, towards the end of her time, in making water, of which she always relieved herself by

raising the tumor." An unjustifiable operation was resorted to in this case, at the time of labour—viz. dividing the neck of the uterus; the child, which had arrived at its full time, was dead born; the mother recovered.

Wonderful as it may appear, that impregnation and the development of the fœtus should take place in a person with a prolapsed uterus, it is almost equally surprising, that in this state the fœtus should be expelled without difficulty. This struck the attention of Harvey*, who mentions the following case of a poor woman who did long labour under the bearing down or precipitation of her womb, to shew, that the uterus has its share in the business of delivery. After trying various means, he says, "and now at this time it [the tumor] was as large as a *bull's cod*, dangling between her legs: so that I suspected, that not onely the *sheath*, but that the *wombe* it selfe was now inverted, or else that shee was diseased with a *uterine hernia* or *rupture*. It grew at last bigger than a *man's head*, being then a hard tumour, and hanging down to her *knees* did much pain her, so that she could not goe (but upon all foure), and breaking just in the bottom of it, it did effund a moisture (as if it had been an *ulcer*) and blood with it. Looking upon it (for I did not explore it by touch) I did suspect it to be a *cancer* of the *wombe*, and therefore did bethink mysele of a *ligature*, and cutting it off: and in the interim, I advised her to apply gentle *fomentations* to it, to assuage the paine. But the following night, an *infant* perfectly shaped, of a span long, was cast out of that *tumour*, but it was dead."

Another striking point connected with this subject is, that the uterus should sometimes be completely prolapsed at the period of its greatest expansion, even during labour. Sabatier†, in an excellent paper on the Displacements of the Uterus and Vagina, says, that when we recal to mind the situation of the womb, the strength of the liga-

ments, whose office it is to keep this organ in its place, and the connexion of the vagina with the surrounding parts, it is difficult to conceive that it should be subject to so extensive a displacement as that of which we have just been speaking. But it is still more difficult to conceive how this displacement should occur during pregnancy, and even during labour. Nevertheless there are several cases of the kind recorded, and he mentions two. The complete prolapsus of the womb could scarcely, one would imagine, be mistaken for any other affection; but it has happened, says Sabatier, that women with precipitation of the womb have passed for hermaphrodites, because the tumor, which escaped from the natural part, had been mistaken for a penis. The shape of the tumor will of course vary in the impregnated and unimpregnated state, but a careful inspection of the part will be sufficient to discover the nature of the complaint.

In my case and that of Gautier before related, the symptoms were slight, and the health of the patient but little affected. In both cases, also, prior to impregnation, the menses were regular, shewing that the displacement of the organ did not interfere with its commonest function. A dragging sensation in the loins, occasional desire to make water, tenesmus, inflammation and ulceration of the most prominent part of the tumor, are the usual symptoms attending this complaint.

The treatment to be adopted in this affection is extremely simple. If the unimpregnated uterus be prolapsed, and the prolapsus has but recently occurred, the part may, in general, be reduced without difficulty or danger; if, on the other hand, the descent of the womb has been of longer duration, and there be much swelling and tumefaction of the part, it is obvious that by the recumbent posture, leeches, emollient applications, support to the part, and proper medical treatment, the inflammation must be removed before the reduction be attempted. The coexistence of pregnancy in this state renders the case more difficult: if the prolapsus occurs in the early state of impregnation, bearing in mind the observations which have just been made, we may endeavour to replace it; but if it occur in a more advanced period, or, as in my case, the surgeon has only the opportunity of

* Exercitationes de Generatione Animalium, London, 1651. I have used the translation published in 1653, 8vo. vide p. 495.

† Sur les Deplacements de la Matrice et du Vagin, in the 3d Vol p. 368, of the *Memoires de l'Academie de Chirurgie*, &c. Also published, with little alteration, in the *Medecine Operatoire*, by the same author, Vol. III. p. 654. Edition of 1824. Vid. also some able articles on this subject in Mr. Samuel Cooper's Dictionary, and in the *Dictionnaire des Sciences Medicales*, t. xxiii.

seeing it till then, any attempt at reduction would be highly improper. I should advise, under such circumstances, the same plan as was adopted in Redburn's case. The treatment to be pursued in a complete prolapsus of the womb at the time of labour, is a subject which I will leave to accoucheurs to determine. I will merely observe, in conclusion, that when the prolapsus has been reduced, and the state of the parts will admit of the use of the instrument, the patient should on no account neglect to wear a pessary, to prevent a recurrence of the mischief.

THE LONDON UNIVERSITY.

To the Editor of the London Medical Gazette.

University of London,
June 7th, 1830.

SIR,

I HAVE read your observations on the late distribution of prizes in the university with much regret. I am sorry to think them indications of feelings towards our medical school on the part of the conductors of the Medical Gazette, which, from whatever source they may have found their way into your columns, do not, I have the gratification to believe, prevail in the profession.

Your remarks on the general state of the university are so evidently founded on incorrect data, that I do not think it necessary to confute them.

What you mean by our ceremonies wanting the dignity belonging to those universities of the "olden stamp," with which your "associations are familiar," I shall not stop to inquire. No one has a truer respect for ancient institutions than I have, but my respect does not amount to worship; and I confess that the simplicity of our ceremonies seems to me quite as interesting as are the pomp, the display, the gorgeous robes, the weighty mace, and heavier Latin, and all the monkish inanities which still encumber those venerable establishments.

You are pleased to express your dissatisfaction with the appearance made by the professors on that occasion; and say, that it suggested the question, "whether the pupils had been attracted

by the accomplishments of their teachers or by the pomp and circumstance of the situations which they held." I am sorry to learn that we appeared to so little advantage; but it is difficult to know what particular accomplishments you expected us to take that opportunity of exhibiting. Recollect, sir, that the professors had been doing their duty during a long session, then just concluded; that such accomplishments as were applicable to their important task had probably been shewn in their lecture-rooms. They had terminated their labours by an anxious investigation into the acquirements of their pupils; and the duty of the 15th of May, as far as the professors were concerned, was simply to deliver a written report, and to name the students who had distinguished themselves. The rest was left to Sir James Graham, and so well performed by him as to have drawn forth the expression of your just approbation. Any attempt at *exhibition* on our part would have laid us open to the charge of quackery, which you have much less justly applied to the conduct of the council of the university.

But these are matters of little importance, and do not require to be dwelt upon. Your objections to the encouragement held out by the university for the better education of medical students, regard the honour of the institution, and demand more consideration.

Allow me to say that you seem to me to have viewed this subject merely with reference to its possible effect on teaching, as a trade; or on particular establishments, as a monopoly.

Although I admit that many eminent persons have always been engaged in the office of teaching in the medical schools of London, it is not to be denied that the medical education obtained in the London schools, generally, is inferior to that for which opportunities are afforded in Paris, Edinburgh, Dublin, or Glasgow, and that London has never held a high rank as a school of medicine. The explanation seems to be found in the peculiar regulations of the London schools. The effect is, that the majority of the London students make a most hurried and imperfect preparation for very important duties. After a very scanty school education, they have many of them been placed as apprentices in the country with those whose harassing engagements left them little time to attend to the professional progress of the

young men entrusted to their care. They acquire, in such situations, certain habits of practice before they know any thing of medicine as a science, which are in reality disadvantageous to them. They then come to London for a few months, in two successive winters, to study anatomy, physiology, chemistry, *materia medica*, botany, surgery, and medicine; and to practise dissection, and to see the medical and surgical practice of an hospital or of a dispensary. In an attempt to crowd so many pursuits into so small a space, some are omitted, all are imperfectly cultivated, and the study of medicine, which should particularly prepare them for the duties they mean to undertake, is generally more neglected than any of the rest. Before they return to the country they are examined by the College of Surgeons and by the Company of Apothecaries, and are expected to shew a certain proficiency in particular branches of medical science; but in the preparation of these examinations they are not accustomed to pay much attention to medicine. Yet this omission is exceedingly important, for the chief business of their lives is to practise medicine, and to act as the physicians in ordinary to the families which they attend.

These are facts known and acknowledged by all; and it is also well known that those general practitioners who have attained great reputation are men who were not content with the common course of a London education, but resorted to the other schools which I have mentioned for further improvement, or prolonged the period of their studies in London. The acquirements of many of them have, in consequence, become the foundation of claims to a higher rank than is commonly accorded to them, or than those of them can support, whose education is strictly limited by the London regulations;—claims not very agreeable, perhaps, to physicians who have acquired their degrees by diligent study, but certainly much strengthened by the degradation which the physicians have long incurred by the venal traffic in medical degrees carried on in certain Universities of the “olden stamp;” the Charters of which ought long ago to have been taken from them, and burnt.

In these circumstances, sir, the Professors in the medical school of the University of London, having no other means of encouraging students, generally, better to qualify themselves for

their duties, have recommended that a testimonial of industry and acquirement, in the form of an honorary diploma, shall be given to such of the medical students in their school as, after studying *three* years, and producing proofs of their acquirements in all the branches of medical knowledge, shall present themselves for it. It is not required that these students shall have remained *with us* one hour longer than most of them now do; it is only required that they shall be industrious whilst they *do* stay with us. It is contemplated that one year of the three will be spent elsewhere, and the student is at perfect liberty to pass that year in any school, at home or abroad.

It really appeared to me, when this matter was in agitation, that the proposition was exactly what the present state of the profession—the present state of medical science—and the present aspirations of the general practitioner, required, as well as most advantageous to the public interests. Far from anticipating such objections as you have discovered, I thought we should be considered, both by the profession and the public, as having shewn a wish to do all the good which it was in our power to do, and in the least objectionable way. After a careful perusal of your remarks, I think so still.

You, however, have overlooked all these considerations. You regard the proposition as involving an assumption of dignity for the benefit of our particular school, and insinuate that we wish to interfere with the College of Surgeons. I am quite sure that our most anxious desire, next to that of being useful to the public, was to avoid interference with any constituted body whatever. Among other parts of our regulations which sufficiently evince this, it is to be remembered, that we do not offer our honours to those who wish to avoid going through the examinations of the College of Surgeons or Society of Apothecaries, but require that the student shall have actually done *more* than they require. If I did not feel assured that you had read our propositions with very little attention, I should be compelled to adopt the suspicion of a wish to misrepresent us, of which I cannot believe you to be capable.

You say that the physicians and surgeons of the Hospital schools should do the same. For the general interest of the profession, I should be very glad to

see them do the same. How the adoption of some such system of encouragement to more prolonged study, at St. Bartholomew's, at Guy's, or at St. Thomas's, or in any other celebrated school, could "degrade science," I cannot understand, and you, I think, would find it difficult to explain.

As I should feel myself disgraced by being mixed up with such designs as you seem to suspect us of, it would give me inexpressible concern to believe that the distinguished members of my profession, who are engaged in the honourable and responsible duties of teachers in London, should fall into those errors into which you have been betrayed. Whatever you may suppose, I trust they will believe, or, at least, that time will prove to them, that although those engaged in the medical school of the University are anxious, and justly anxious, for its success, and will spare no pains to ensure that success, they do not consider themselves engaged in a miserable rivalry with the other schools, much less engaged in any unworthy hostility: I lament to see your pages made instrumental in raising up such feelings.

For myself, I can truly say, that I consider it no less an honour to belong to a class of men containing so many accomplished physicians and surgeons as are numbered among the London lecturers, than I do to be associated with my learned colleagues in the University; that I look upon myself as engaged in one common cause with all medical teachers, without reference to any particular school; and as having incurred, like them, a solemn engagement to cultivate medical science with industry, and to teach it with sincerity. If the time should ever arrive when those engaged in the medical school of the University should aim at success in any other way, I, for one, should cease to wish them to attain it.

I have the honour to be, Sir,

Your very obedient servant,

J. CONOLLY,
Professor of Medicine.

[We have given immediate insertion to Dr. Conolly's answer: on another occasion we shall probably offer some remarks in reply; meantime we refer to the piece of intelligence at page 411, of which we were ignorant at the time our article of last week was written, otherwise we would have alluded to it.]

COLLEGE OF PHYSICIANS.

Monday, May 31.

DR. ROBERTS IN THE CHAIR.

On the Cure of Habitual Constipation.

DR. F. HAWKINS read a paper "on the Cure of Habitual Constipation, or on the method of obtaining an effect gradually more powerful by the repetition of any purgative in the same dose," by Mr. Chevalier. Mr. Chevalier was led, by reasoning on the effects of sulphate of quina in certain ulcers, (namely, that of converting purulent into mucous discharge) to infer that its agency was that of a tonic rather than an astringent; that, in short, it invigorated the action of the part to which it was applied. Pursuing this idea, he supposed that if given in combination with purgatives, it might act in the same beneficial way upon the bowels in habitual constipation. The results of more than five years extensive trial has convinced him that any sufficient purgative, in conjunction with the quina, being continued for a due length of time, will produce "an undiminished and uniform effect," requiring no increase of dose; and in process of time producing a more powerful effect than at first, so that the dose of the purgative may be gradually diminished, and ultimately dispensed with altogether.

The following are the formulæ which he has found most convenient; the former for adults, the latter for infants under one year.

R Quinæ Sulphatis, gr. xxiv. Pilulæ Cambogiæ, comp. gr. xxxvi. M. fiant pilulæ equales, xii.

R Pulv. Ipecac. gr. ʒ. Hydrarg. c. Creta, gr. ii. Quinæ Sulphatis, gr. ss. Magnesiae, vel Pulv. Rhei, q. s. M. To be taken twice or three times a-day.

On the Effects of Piperine in Intermittent Fever.

The above was followed by some observations "on the effects of Piperine in Intermittent Fever," by Dr. Roupell. The author began by observing that those practitioners who had only seen ague as it appears in London, might be disposed to question the necessity for seeking after new remedies for it; but they who knew how difficult it was to deal with the disease in those situations where the poison continues still to be applied—

who had seen "the failure of bark in all its forms—even quinine defeated, and arsenic inert," would be ready to avail themselves of any addition to the means of cure. Such an auxiliary, Dr. Roupell is convinced presents itself in piperine. The author then related several cases in which it had proved efficacious in doses of from one to two grains, repeated at various intervals. The objects in view in this paper were to point out the efficacy of the remedy, its superiority to quina, and its power of controuling the paroxysm when exhibited immediately before it.

Piperine, according to M. Pelletier, is a resin with some peculiar characters, being the active principle of the black pepper long used as a popular remedy in ague. Pill is the only form in which piperine can conveniently be given: the expense of the preparation, however, which considerably exceeds that of quina, at present forms a bar to its general adoption.

ROYAL INSTITUTION,

Friday, May 23, 1830.

B. B. CABELL, ESQ. F.S.A. VICE-PRESIDENT, IN THE CHAIR.

Captain Manby on the means of preserving lives in cases of Shipwreck, and on a new practical mode of hauling Life-Boats through the Surf.

THIS veteran philanthropist, whose plans have been long before the public, feeling, as he observed, the old man creeping on him apace, and being anxious still further to promulgate a plan by which nearly 500 lives have been already saved, gave this evening a description of his apparatus and the mode of using it, illustrated by models, and as far as possible by experiment. The principle consists in projecting a shot, to which a rope is attached, from a mortar, over any vessel in danger, by which a communication may be established with the land; and with such precision can the rope be cast that the Captain stated he was in the habit, when the crew were lashed among the rigging, of saving first those who appeared most feeble. The shot, which consists of a bored sphere, can be thrown 476 yards, and lives have been saved at the distance of 240. The mortar, shot, ropes, &c. are all kept in readiness on a truck at the several stations on the coast, so as to be always immediately at com-

mand when necessity requires. A point of chief importance is the mode of laying the rope so that there may be no sudden or acute turns, which almost inevitably cause it to snap, and this invariably happens if common chains be used. During the darkness of night the position of the vessel in distress is ascertained by the projection of a paper shell, containing 200 or 300 stars, and the direction marked by two upright poles. After paying a just meed of praise to Mr. Winn, a shipwright of Yarmouth, who, half a century back, conceived the idea of rendering assistance to vessels in distress by making all ships carry floating ropes, *i. e.* ropes charged with corks, which were to be cast overboard in hope one would float to land; and to Lient. Bell, who designed to establish a communication with the shore by firing from the ship, and having shewn that both those means were impracticable, he claimed for himself the invention which goes by his name, but which has in some cases been, as he thinks, unjustly contested.

He has printed directions for the most effective manner of proceeding, and has invented a series of telegraphic signs, consisting of various positions of one or both arms, by which commands may be conveyed from the shore to the ship or from the vessel to the land.

In the library were several large Chinese paintings, which would seem to indicate some advancement by that nation in the fine arts, for one or two of them were evidently caricatures of their European visitors.

We were much pleased with a very convenient application of the mode in which small insects, &c. for the microscope, have long been preserved between two plates of glass, or one of glass and one of talc, to the purposes of vegetable anatomy. The parts of plants are so minute and delicate that preparations of their intimate structures can scarcely ever be put up in the ordinary way; but vessels the most delicate may be preserved by placing them on a small strip of glass, and surrounding the dissection with a layer of white lead, so as to form a minute basin; this should have a drop or two of spirit put in, and then a layer of talc, or another of glass being super-imposed, the preparation is complete, and can be kept for any length of time for future reference.

MEDICAL GAZETTE.

Saturday, June 12, 1830.

“ Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”—CICERO.

THE KING.

WE have received numerous requests to afford some particulars of the King's illness. It is obvious that were we in possession of the information required, it would be indelicate and improper to enter into details. Neither, indeed, is there any thing remarkable in his Majesty's case, or different from other instances of organic disease in the chest ending in dropsy; unless, indeed, it be the manner in which the royal patient has several times rallied when the fatal result seemed to be imminent;—a circumstance chiefly to be attributed to the skill of his attendants, and the unremitting attention with which he is watched. We understand that the most powerful diuretics having failed to produce the desired effects, and the serous effusion continuing to accumulate, in spite of the artificial means adopted for its exit—the permanent difficulty of breathing has increased to a most distressing extent, and become attended with great anxiety and exhaustion. Every means, which science can suggest has, of course, been adopted to relieve the royal sufferer: among these, the most successful in procuring sleep and intervals of ease, have been opiates, and, we believe, among others, morphia; while the more violent paroxysms of impeded respiration have been in some degree mitigated by the volatile alkali, and other diffusible stimulants.

HIS MAJESTY'S PROFESSIONAL ATTENDANTS.

WE would not mix up our notice of the royal patient with any allusion to the infamous attacks which have been made upon his medical attendants; but the honour of our profession requires that we should not suffer them to pass unanswered.

It was asserted in the *Lancet* last week, and the statement was copied into several newspapers, that one of the physicians had signed the bulletins without seeing his Majesty, and of course without being personally acquainted with the circumstances to which he certified: in short, that “Sir Matthew Tierney, although his *name* has regularly appeared, was not consulted by, nor even did see his Majesty, for nearly twelve days.”

It is difficult to conceive a graver charge than this, or one made with more circumstantial and deliberate minuteness of detail than appears in the paper from which it is taken. Yet do we pronounce a contradiction, as strong and unequivocal as words can make it—that the accusation is a gross and malignant falsehood, which the general tenor of the article that contains it leads us to fear is intended to serve some intriguing party and personal purpose. This story comes from the same quarter, and has precisely the same claim to our belief, as that about Sir Astley Cooper, which we proved, as well by the official statement which we published last week as by the letter of the distinguished surgeon alluded to, to be “without any foundation in truth;” and with regard to the present calumny, we pledge the character of our journal for our accuracy, in asserting *that it is wholly without foundation, and as false in statement as it is scandalous in design.*

We would also willingly remove the idea which the *Lancet* has been so anxious to propagate, under the flimsy

pretence of respect for his medical skill—that some slight has on this occasion been shewn to Sir Astley Cooper. Now we would remark, that when, on the 6th of June, 1829*, we find Sir Astley compared to “Dr. Eady, of Church Street, Soho,” who is represented as shewing professionally “an example worthy of speedy imitation to the SERJEANT-SURGEON of our King;” and when, on the 5th of June, 1830—being precisely one year after—we find the same writer speaking of the distinguished Baronet in terms of eulogy which form such a contrast to the unmeasured insolence of his former lucubrations—we say, that when we observe this extraordinary contrast, we may fairly question the sincerity of a writer whose opinions have undergone so great a revolution. Here, however, our principal object is to correct the error, because it has appeared in several respectable papers, and among others in the *Courier*:—it is not correct to say that Sir Astley Cooper has been *superseded*, for he has not recently been in attendance. In fact, Sir Astley has not been consulted by the King since he was elevated to the rank of “Serjeant-Surgeon;” at which time Mr. Brodie and Mr. Wardrop were appointed “Surgeons to the Body.” It is the specific duty of the *Serjeant-Surgeon* to attend the King when he goes to battle, and hence the military turn of the phrase—while it is the business of the Surgeons to the Body to visit him on ordinary occasions. His Majesty’s present malady is one of those which is allotted to physicians, but which happens to require the assistance of a surgeon to carry some of the necessary measures into effect:—and it is remarkable, that while Mr. Wardrop was supposed to be in attendance, the *Lancet* was perfectly satisfied with the arrangement. Had his Majesty’s

case been surgical, then, of course, more than one eminent surgeon would have been consulted, and their names would have been attached to the bulletins. Probably, under such circumstances, Sir Astley Cooper’s assistance might have been required; but his holding the office of Serjeant-Surgeon does not, by any means, make this a matter of course:—the late Sir P. Macgregor, for instance, who held the office of Serjeant-Surgeon, never was consulted by his Majesty.

RESIGNATION OF MR. C. BELL.

It has been generally rumoured, within the last few days, that Mr. C. Bell has resigned his professorships in the London University. We are enabled to confirm this, and to state, that his resignation was tendered six months ago. His reasons are understood to be the impossibility of realizing those prospects which he held out to the medical pupils, in his first lecture, at the opening of the University.

HYDROPHOBIA.

WE were inclined to hope that the alarm on the subject of hydrophobia had been very much exaggerated. We think it right, however, to state that we have instituted some inquiries upon this subject, and find that, at one of the veterinary establishments at the west end of the town, not less than sixty rabid dogs have been received during the last three months; being a number greatly exceeding what has been met with during any former season. It appears, indeed, to prevail epidemically, and not to be much, if at all, connected with the state of the weather—at least as to heat. We saw two mad dogs and a hydrophobic cat, at Mr. Youatt’s, in Nassau-Street, all at the same time, during the coldest part of last winter. The best thing which persons having dogs which they are unwilling to destroy can do, is to send them to a veterinary infirmary the moment they shew the least symptom of illness. If it prove hydrophobia, they are prevented from doing harm; and if not, they are taken care of till they recover. As to the numberless remedies which have been published within this fortnight, there is not one of them

* See *Lancet* of that date, page 302.

good for any thing; indeed, they are calculated to do harm, by leading persons to place confidence where they will not find safety. There is no cure, and but a short period for prevention. We have known the disease come on though the part was cut out within half an hour after the receipt of the bite: the excision ought, therefore, to be *instantaneous*.

HOSPITAL REPORTS.

LA CHARITÉ.

Hæmatemesis produced by the rupture of a branch of the Coronary Artery of the Stomach.—Death.

LOUIS PETIT, æt. 29, admitted April 30. By trade a carpenter, of sanguine temperament, addicted from childhood to intemperance and excessive use of spirituous liquors. Was seized five years ago by vomitings of blood, which continued for eight days, returning during that time every night at the same hour. The remedies he took, including astringent drinks, stopped it at this time, but the patient was so much exhausted with the loss of blood that he was confined to his bed for two months.

On his recovery, notwithstanding the warnings of his medical attendants, he drank as much brandy as ever, without, however, materially affecting his health.

April 13, 1830.—He began to feel heat and pain in the epigastric region; he almost entirely lost his appetite; and in the evening of the 30th, on returning from his work, a general feeling of illness obliged him to take to his bed, and immediately afterwards he vomited a quantity of blood, estimated at five or six pounds: he was immediately taken to the hospital. No blood was abstracted from the veins, his pulse being small and easily compressed, and he appeared quite exhausted. Mustard poultices were applied to the feet.

May 1st.—During the night the patient vomited, but not abundantly; the pulse has risen, and he is recovering strength. Hirudines xx. to the epigastric region, low diet, and an emulsion of gum and syrup of quinces.

8.—Yesterday evening the patient had a return of the hæmatemesis, and vomited a considerable quantity of blood. His general state is not altered; bowels confined. Twenty leeches to the anus. Continue emulsion.

At five o'clock in the afternoon, a return of the hæmorrhage, more violent than the preceding, brought on great prostration of strength, and at ten he died.

Post-mortem.—The excessive paleness of the stomach and small intestines contrasted strongly with the redness of the large. The stomach contained a sanguineous liquid, in which a few clots of blood were floating. About three inches from the cardiac orifice an ulceration was found of nearly three lines in depth and six or seven in diameter; its edges were thickened, and had a scirrhous feel, formed by the condensed cellular tissue and muscular membrane; in the centre was a conical prominence, at the top of which was a clot of blood, half an inch in length when drawn out. A probe carried into the cavity of the coronary artery, on the external surface of the stomach, was carried into the centre of the prominence, and pushed out the fibrinous plug which closed the opening. The probe, while carried along the under surface of the ulcer, entered a second canal diametrically opposite to the first; it was, in fact, the same artery nearly divided by the ulcerative process, but still connected by a filament of the arterial coat. The rest of the mucous membrane of the stomach was unaltered either in texture or colour.

It is remarkable in this case that the whole ill effects of his indulgence in spirituous liquors should be confined to a single spot of the mucous membrane of the stomach, while his general health did not appear in any degree injured. It is also extremely difficult to account for the manner in which the hæmorrhage stopped after eight days, since it appears that a rupture of the artery then, as later, must have been the cause of it. Ordinarily, however, in these cases a return of hæmorrhage takes place at short intervals, whereas here for five years he was entirely free from all symptoms of it. Could the astringents have in any way effected the plugging of the torn artery by a clot of fibrinous coagulum? It is rather a peculiar case, and seems well worth recording.

Case of a Rib affected with Caries being Dissected out.—Death of the Patient.

Louis Evrard, æt. 38, admitted March 23, 1830, with a small fistulous ulcer

above the fifth rib of the right side, from which had been discharged for some time purulent matter in abundance.

A probe, passed under the skin in the sinuss, seemed directed to the fifth rib, near its centre, and which appeared rough and denuded, but it seemed difficult to determine whether the disease was necrosis, or caries of the bone, the history of the patient giving but little assistance.

The patient was thin, emaciated, suffering from severe cough, attended with thick mucous but not purulent expectoration; on the contrary, the matter discharged from the fistula was decidedly purulent; consequently they were very distinct from each other, and hence all idea of connexion between the surface of the bronchi and the lining of the ribs was dismissed.

On the 24th of April, M. Roux proceeded to dissect the rib out, after having taken every means to convince himself that the disease had only attacked that bone in the centre, and that those of the other side were free. The operation was performed in the following manner:—

The whole of the soft parts, covering as much of the bone as was affected, was surrounded by two semi-elliptic incisions, passing immediately under the right nipple, and extending to the sternum. The chain-saw was then passed by means of Deschamp's seton needle to the two extremities of the diseased bone, and about four inches were taken out. The part, however, next the sternum not appearing sound, a still farther portion was taken off with a circular saw. The pleura costalis was naturally adherent to the inferior border of the rib, but at the superior it had been separated and pushed in by an accumulation of putrid pus. M. Roux convinced himself that this did not communicate with the interior of the chest, and he could discover no further mark of disease. It was then dressed simply, and during the next two or three days the wound looked well, and the patient's cough was less painful, though quite as frequent.

On examining the bone, it was found to be in a state of true caries; the superior and internal surface especially were rough, and entirely denuded, and becoming gradually less diseased as it approached the extremities.

After the second day oppressions and

pains in the side became more serious, and the patient rapidly sunk with symptoms of pleurisy of the right side.

Post-mortem.—The right cavity of the chest contained a considerable quantity of sero-purulent fluid and some albuminous flakes, all apparently of recent formation: the two inferior thirds of this cavity were filled with the fluid, but above it required some force to separate the lungs, on account of old adhesions, and the tearing that resulted shewed the lung all studded with tubercles in an advanced stage, and the internal surface of the fourth, third, and second ribs disorganized by caries; and the points where this disease was most advanced, were those which corresponded with the tuberculous masses. The caries extended to the posterior part of the ribs, which broke with great ease; it was worthy of remark, however, that the portion of pleura from whence the rib was taken, appeared perfectly healthy, and had formed no adhesion with the membrane lining the lung. The tubercles had not suppurated in any part. There was nothing remarkable in the other organs.

NOTTINGHAM HOSPITAL.

Case of large Tumor in the Thigh containing Hydatids.

ALICE LEE, æt. 14, admitted March 24th, 1850, under Mr. Attenburrow, for a tumor occupying a considerable portion of the right thigh, on the upper part, and principally on the inside.

She states, that about eleven months since, in consequence of an alarm being given that the house was falling while she was at work in an upper room, she hurried down, and in her endeavour to escape fell down a flight of stairs, and was taken up nearly insensible. She did not then complain of any local injury, but next day, on sitting down, experienced pain in the calf of the right leg, and a sensation as of something tearing. Much attention, however, was not paid to it, either by herself or friends. About a month afterwards she discovered a swelling on the middle and inner part of the thigh, near the edge of the sartorius. It is described to have been the size of a large orange, but flattened. Advice was then procured, and leeches, lotions, and liniments applied; and at a later period tight bandaging was tried without any beneficial effect, the tumour rapidly increasing in size.

The tumour is now enormous, extending from the pubes and right inguen downwards

for two-thirds of the thigh, and spreading across the limb. She is free from pain, and none is caused by pressure. No œdema of the leg or foot; pulsation in the ham not very distinct; general health good; catamenia regular; she is very active. The circumference of the affected limb is twenty-eight inches, that of the other sixteen. Length of the tumour, from the pubes downwards, twelve inches; breadth, from base to base, nineteen; circumference, taken at its base, thirty-three. It has a tense and elastic feel, and communicates a sensation of fluid, though no fluctuation can be distinctly ascertained. The sensation to the touch is similar to that of fungus hæmatodes, except that there is an evenness of surface not generally accompanying that disease. The superficial veins are not enlarged; the integuments have a mottled appearance; no pulsation was ever observed.

A consultation was held on the day of her admission, in which Mr. Attenburrow expressed his opinion that the tumour consisted of a deep-seated cyst with fluid, probably containing hydatids; in which he was joined by Mr. Oldknow, and it was decided that an opening should be made into it.

March 26th.—A large trochar was pushed into the body of the tumour, towards its inferior edge, where the integuments appeared thinnest; and on withdrawing the blade a quantity of dark coloured matter poured out of the canula: the stream was occasionally obstructed by large portions of broken down hydatids. On gathering up the integuments with both hands, with a view to prevent the admission of air as the cyst was emptied, and to evacuate it as much as possible, strong pressure was made, and several times the bursting of a hydatid was sensibly felt, and invariably followed by a discharge of clear serum, which was again succeeded by hydatid cysts and purulent fluid. When the cyst seemed fairly emptied, a bandage was lightly applied from above downwards, and below upwards; and over the opening a plaister bandage, so as to surround the limb, and make regular and firm pressure over the whole circumference of the tumour.

The quantity of fluid discharged was seven pints. The patient was sent to bed without having experienced the least faintness.

On being visited the next morning, she said she felt quite well. The pressure of the bandage on the upper part of the limb caused a little uneasiness, which was relieved by a few rounds being cut through.

27th.—Passed a good night; does not complain of any uneasiness.

29th.—On removing the bandage to-day there was no appearance of discharge nor any fluctuation. The whole of the thigh, from the knee upwards, ordered to be strapped with plaister bandage, firmly and regularly, and covered with a roller.

April 1st.—Appears quite well. On examining the limb, no irregularity or local indication was observable, and the thigh appeared in its natural state, with the exception of a fullness, as though the loose sac still remained. Bandage to be re applied.

9th.—Bowels have been confined, and required several doses of medicine before they acted. The fullness alluded to is now rather more perceptible; it may be pushed up or down, and appears to contain some fluid.

13th.—She walks about, and there is no perceptible increase of swelling.

19th.—She has been up, and using exercise. There is now evident accumulation of fluid in the sac, at the upper part of the thigh.

24th.—About a pint and a half of purulent fluid was discharged by a free opening made to-day, which was then closed as before.

25th.—Complains of some pain in the limb, and is rather feverish. *Samatur haustus* purgans. Pulse quick; feels thirsty.

26th.—Quickness of pulse, thirst, and general symptoms of fever still continue.

Cap. Mist. Alkal. cum Pulv. Acid.
Tart. ter die.

28th.—Quite free from fever; limb easy.

May 4th.—Limb quite easy; no apparent increase of size.

24th.—The limb continues its natural size; the bandaging is still continued, and she enjoys good health.

There are several peculiar circumstances in the history of this case, making it one of considerable interest. In the first place, from the slight attention either the patient or friends had paid to it in its early stage, no accurate information could be obtained as to its mode of development. Then again, the tense and elastic feel which accompanied it, without any fluctuation being appreciable, made it doubtful whether it might not be of a fungous character. Mr. Attenburrow, however, after the first careful examination which he gave it, expressed the opinion we have already stated as to its nature; the truth of which was singularly well borne out, in every particular, by the result.

NORFOLK AND NORWICH HOSPITAL.

Fractured Neck of the Scapula.

JOHN HARRISON, æt. 85, an active old man, was admitted on the 13th September, 1828, into this hospital, under the care of Mr. Cross. On examining the seat of injury there was much the appearance of a dislocation of the left shoulder; viz. loss of its roundness from sinking of the deltoid muscle,

and the head of the humerus felt in the axilla. He stated that he met with the accident from a fall in the street a fortnight before. As far as could be ascertained, the blow was received upon the shoulder, and the arm was not extended at the time, as it usually is when a dislocation has taken place. He had gone about without much pain, and had sought no advice respecting his case till a day or two ago, which he was induced to do at that time, because the arm and hand had become much swollen and oedematous. By raising the shoulder, the bone was moved into its place, but it sunk again as soon as the support was removed. This explained the nature of the case, and in corroboration of its being a fracture, a crepitus was felt by placing the hand on the shoulder and raising the arm. The coracoid process also fell, and became imperceptible to the finger, when the shoulder was allowed to sink. A roller having been applied to the forearm and arm, the fractured bone was reduced by raising the humerus, whilst parallel to the chest, and drawing its head outwards. It was maintained in this position by a conical pad, the base of which was placed in the axilla, and fixed in that situation by tapes crossing on the shoulder, and tied on the opposite side. A roller round the body and arm kept the elbow applied to the chest, so as to throw the head of the humerus outwards.

Oct. 30th.—The bandages have been renewed every week or ten days, and the patient has been walking about well during the whole time.

Nov. 6th.—The limb has been supported with the sub-axillary pad and bandages up to this time, and on removing them to-day, the shoulder is found to have a good rounded shape, and is firm, as if union had taken place, but the apparatus is to be applied for another week.

14th.—The pad and bandages were removed to-day, and the shoulder is perfectly rounded and well-shaped. The limb bears to be moved freely; and as there is no doubt of firm union having taken place, the man is discharged. Two months afterwards, Mr. Cross stated that he saw him enjoying full and free motion of the injured shoulder.

Two days previously to admission, the patient applied to a surgeon for relief, who, after a slight examination, sent him to the hospital under an idea that he had met with a dislocation of the humerus into the axilla. The similarity, in appearance, which the two accidents usually present, readily leads to the occurrence of such a mistake, which, however, may easily be obviated by a strict and minute examination, and by attending to the circumstances pointed out in the relation of this case, viz. the ease with which the parts are brought to their proper position; the return-

ing of the deformity as soon as the limb is left unsupported; and the falling of the coracoid process along with the limb, so as not to be felt in its usual situation.

GUY'S HOSPITAL.

Case of Fungoid Disease of Sacrum, &c.

W. PAGE, 19 years of age, admitted 25th March 1830. About two years ago became out of health, and perceived a lump over the sacrum, which was painful; the pain occasionally shooting down the course of the sciatic nerve to the toes. The tumor gradually increased with the same symptoms till a fortnight ago, when the pain in his legs became so severe as to render him unable to use them.

He now lies on his side, or on his belly, with the knees drawn up. There is an irregular swelling on the sacrum, its right end as large as a small orange, its left diffused over the ischiatic notch and less elevated, and the two connected by a flatter band across the spines of the sacrum, which cannot, in consequence, be felt. The whole has the peculiar elastic feel of fungus hæmatodes, and is slightly painful on pressure; otherwise there is only occasional shooting pain there.

The finger *in recto* detected a lump like a goose's egg in the hollow of the sacrum, though the patient says he has never had much difficulty in passing his motions, his bowels only requiring occasional laxatives, and there being no pain in going to stool. He is obliged to strain some time before he can make water; and frequently it is otherwise, the urine passing away spontaneously in bed. There is a hard swelling behind the pubes connected with the bladder; this goes down when the bladder has been emptied, but is obviously something more than an ordinary distended bladder. The pain in his legs is like cramp, with occasional exacerbations.

Tongue clean; pulse 104, natural force; bowels confined.

Hæbeat Ol. Ricini, ʒss. p. r. n.

30th.—The bowels act easily after the castor oil. The pain in the left leg and thigh is most severe; it is increased on the least motion, and hence he keeps the knee drawn up to his body; he can get no sleep in consequence.

Tr. Opii, ℥xx. p. r. n. horâ somni.
Applicatur Tr. Iodini tumori.

1st April.—Caught cold last night, and now, in addition to his former sufferings, he has a severe inflammation of the tonsils.

[This was treated on ordinary principles, and soon gave way to leeches and astringent gargles, &c. The pain in his leg also dimi-

nished, so as to enable him to sleep comfortably without the laudanum.]

12th.—Complains to-day of severe pain down the inner side of right thigh, as far as the knee.

Habeat Tr. Iodini, ℥viii. ex Infus. Rosæ c. bis die.

19th.—Tumor is much increased in size, and the pain down both thighs is very severe. In the right it is confined to the inner side of thigh down to the knee, and depends probably on pressure of the obturator nerve by the tumor within the pelvis. On the left side it passes down the back of the thigh, and is severely felt at the extremity of the toes. This evidently arises from the pressure of the tumor on the sciatic nerve.

Bowels not open without aperients. Castor oil makes him sick. To have instead—

Pil. Aloes. c. Myrrhā, gr. xv. pro re nata, et continuet alia.

24th.—Right leg slightly œdematous; is much weaker. To have a pint of ale daily.

3d May.—Pain intermitted for two or three days, but is now as bad as ever. Tumor larger and softer. Health keeps up, but he gets weaker every day.

To have ʒij. of wine in addition to the ale, and a chop.

5th.—Last night in making water he felt something “give way” within, and there followed a good deal of thick bloody matter, which was thrown away by nurse before any one else saw it.

8th.—There has been no more of the discharge. Since it took place he has entirely lost the pains down his thighs, and can now make water comfortably, without pain, and when he likes; bowels open four or five times a-day; tongue rather coated, not dry; pulse 96, quick; face pallid and anxious; skin dry; abdomen remarkably hot; shrinks from pressure in *epigastrio*, where, he says, is his only pain; he takes wine and nourishment—arrow-root, &c. with good appetite.

Ordered.—Fotus Abdomini, et Tr. Acetatis Morphiæ, ℥xxv. o. n.

13th.—Pain in belly remains, but is not increased on continued pressure. Has had ʒij. of brandy for the last few days in addition to the ale and wine, but has no appetite for solid aliment. The tumors behind are at least four times as large as at the time of admission, and the pain in the thighs has returned. He is much worn down by suffering, and is daily getting more low.

17th.—He died early this morning.

Examination, 3 hours afterwards.—Chest: There were a few small tubercles in both lungs, chiefly superficial, otherwise the lung was sound; heart healthy. Abdomen; Peritoneum and viscera generally quite natural. The pelvis was occupied by a considerable number of tumors, growing apparently from the sacrum and os coccygis, and spread-

ing in different directions; a vertical section, however, of these two bones shewed that the bones themselves were free from the disease, (except a little of the upper part of the coccyx,) which appeared to originate in the ligaments connecting them. Behind, also, the tumors had arisen from the ligaments of the sacrum and coccygis, and had spread laterally, making pressure on the ischiatic notches.

A section of the tumors shewed them to be made up of a number of nodules, which, with the subordinate tissue, was supposed by Dr. Hodgkin to consist of cysts. There was no bony matter in them; they were remarkably soft and cerebriform, intermixed with streaks of white and patches of yellow, together with clotted and extravasated blood.

One of the tumors within the pelvis, arising from the os coccygis, had pressed forwards on the rectum, just above the anus, so as considerably to obstruct the calibre of the gut.

NEW TREATMENT FOR ENLARGED TONSILS.

WE observe, in the French journals, the administration of calomel advocated as acting with almost more than a specific charm, in the treatment of inflammatory enlargement of the tonsils. Four cases that are given in the *Journal Hebdomadaire* are certainly sufficiently conclusive, having effected a total cure alike of the inflammatory action and the enlargement in less than thirty hours, and considerable relief within the first five! This seems very much to partake of the marvellous; however they are clearly related by M. Scille Mondezert, and as he only recommends grain doses six times a-day, no inconvenience or danger can accrue from the trial.

BOOKS RECEIVED FOR REVIEW.

A short Treatise on Operative Surgery; describing the principal Operations as they are practised in England and France. By Charles Averill, Surgeon to the Cheltenham Casualty Hospital, &c. &c.

A Popular Description of the Aldinian Defensive Dresses, &c. &c. for rescuing Human Life and Property from Injury or Destruction in Cases of Fire.

Flora Medica, No. 31; containing Botanical Descriptions, Natural History, Chemical Properties and Analysis, Medical Properties and Uses, &c. &c. &c.

ERRATUM.

In our leading article last week, p. 331, for “extremity of weakness,” read “extreme of weakness.”

LECTURES ON SURGERY,

Delivered at St. Bartholomew's Hospital,

BY WILLIAM LAWRENCE, F.R.S.

LECTURE L.

Recapitulation.—Fracture of the Clavicle—of the Scapula—of the Humerus—of the Fore-arm—of the Carpus, Metacarpus, and Fingers.

In the last lecture, gentlemen, I mentioned to you the necessity of observing absolute quietude in cases of fracture of the spine, in order to favour the consolidation of the bones, and to diminish the effects of the inflammation of the surrounding parts, and the disturbance that might arise from that cause. But where the vertebral column is injured high up in the neck, the necessity of absolute quietude is still more obvious, because a slight degree of motion, under such circumstances, will sometimes be attended with a sudden and fatal pressure upon the spinal cord. The fractured portions in the neck are much more loose and moveable than in the case of fracture occurring either in the back or in the loins; and thus it will happen that if the head of the patient be incautiously raised, or if the patient be moved from the recumbent to the sitting position, the upper fragment may slip forwards upon the lower, and produce pressure upon the medulla spinalis.

Within the last two or three weeks I had a patient under my care in the hospital in whom this accident took place. The exact situation of the fracture was not apparent, but it was clear that it was high up. Some friends of the patient came to see him one evening, and he was very desirous of being moved a little—from the irksomeness of remaining in one position; and having expressed this wish to his friends, they raised up his head and brought it forward; the consequence was, that he died instantly. I suppose the case would have been equally fatal

if this had not happened; but of course it is well to avoid an occurrence of this kind.

Fracture of the Clavicle.

When you consider the form, position, connexion, and the office of the *clavicle*, you will not be surprised at finding that it is very frequently fractured. The clavicle is rather a slender and elongated bone. It is seated at the upper and anterior part of the chest, where it is covered simply by the integuments, so that in fact its outline is distinctly visible through the skin. It is placed between the sternum and the scapula, to both of which it is articulated, and it serves to keep the scapula, and through it the whole of the upper extremity, at a proper distance from the sternum. But for this bone, the scapula and the upper extremity would come forwards towards the anterior part of the chest; and the situation of the scapula, if it were not for the clavicle, would correspond to that which it holds in animals in whom the anterior part of the trunk is supported upon the fore legs. The clavicle is a kind of *pivot*, on which the upper extremity turns. From this circumstance the clavicle is liable to be fractured by direct violence, that is, by blows inflicted immediately upon the bone itself. It is also liable to be broken in consequence of violence communicated to it through the medium of the upper extremity. Thus, when a person falls to the ground and stretches out his arm to save himself, if he fall either upon the shoulder, the bend of the elbow, or on the palm of the hand—in either of these cases the clavicle is included between two forces, and frequently gives way at the weakest part, which is generally towards the middle.

Generally speaking, the fracture of the clavicle is *single*, that is, the bone breaks at one part only; but in the case of a direct blow, the fracture may be comminuted, that is, the clavicle may be broken in more places than one. Under such circumstances there may be much bruising and ecchymosis of the surrounding parts. By such direct

blow the comminuted parts of the clavicle may be depressed upon the axillary plexus of vessels and nerves, and may produce symptoms referable to pressure on those parts. Fracture of the clavicle may be either single or compound,—the latter, however, very rarely occurs. I lately had a case under my care in the hospital of compound fracture of the clavicle, where the opening in the integument was small, seated at some distance from the fracture. When the bone was reduced the wound in the integument closed very easily, and then the case proceeded as a simple fracture of the clavicle.

When the clavicle is broken, it depends upon the situation of the injury whether you will have any considerable displacement or not. If the fracture take place at the scapular end, that is, about an inch or an inch and a half from the articulation which joins the bone to the scapula, you will have no displacement, because the under surface of the clavicle is there closely connected to the root of the coracoid process by a ligament. Likewise, if the bone is broken through the thick part very near the sternum, in general the fragment is not displaced. But these are the least frequent situations of fracture of the clavicle; it more commonly gives way in consequence of the application of force from the two extremities which tends towards the middle, and then a greater or less, and in some instances a pretty considerable displacement of the fractured ends takes place. When the clavicle is broken, the shoulder being no longer retained in its proper lateral situation, it advances towards the sternum; the shoulder moves inwards towards the middle of the body, and thus carries the scapular end of the fragment under the sternal end. The shoulder also sinks, for the clavicle forms a support to the upper extremity; so that when this is broken through, the weight of the limb occasions the upper end of the clavicle to be displaced downwards: the shoulder sinks and becomes lower than before; in other words, the scapular end of the clavicle is displaced downwards as well as inwards. The principal displacement is inwards, towards the sternum, and it necessarily occasions a riding of the bones.
